Local treatment through the duodenal tube connected with a Murphy drip has been employed by me with marked success. This method consists in passing a duodenal tube in the usual way and after obtaining bile the end of the tube is connected with the Murphy drip and the medication or cleansing solution allowed to run through at a rate of from 40 to 60 drops a minute. When bile can not be aspirated I employ a 25 per cent. solution of magnesium sulphate which, according to Meltzer, causes a complete local relaxation of the intestinal wall, relaxes the sphincter of the common duct and permits the ejection of bile, and in some cases permits the removal of a calculus of moderate size wedged in the duct in front of the papilla of Vater. The various solutions are used according to their purposes. Solutions of the various silver preparations, such as argyrol, protargol, and even nitrate of silver, may be used. Methylene-blue, salicylic acid, and urotropin have also been employed by me. As a rule these disinfecting solutions should be used in a concentrated form to prevent absorption from the intestinal tract. Concentrated solutions of sodium bicarbonate, sodium phosphate, sodium sulphate, and fairly strong dilutions of liquor antisepticus alkalinus may be employed for their cleansing and mucus-dissolving action.

Externally hot applications to the epigastrium or the hepatic region are valuable. Hot compresses and fomentations should be ordered for the patient's use at home. Heat from a therapeutic (carbon) lamp followed by high frequency currents applied over the hepatic region and epigastrium have given satisfactory results.

HUMPED, HOOKED, AND BULBOUS NOSES: THEIR ETIOLOGY AND TREATMENT.

By WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.,

NEW YORK.

THE true aquiline nose is curved like the beak of an eagle; it is hooked at the extremity, and is frequently bulbous at the tip. In its exaggerated form it constitutes a deformity which we must all frankly admit is a menace to the happiness and in many an instance to the business prospects of its possessor.

On account of general familiarity with the deformity and other equally laudable considerations, I have decided not to demonstrate results in this presentation of the subject by means of photographic illustrations. I may state, however, that in all of my cases the deformity has been corrected, and that neither at the time of the operation nor subsequently have undesirable complications arisen. The ease, safety, and certainty with which this defect may be remedied induce me to bring before my readers the methods I have used successfully in correcting so many of these cases.

The aquiline deformity is strongly characteristic of certain races, but in some families, without racial inclination, there is a predisposition to its development. Trauma, especially repeated injuries as in football players, is unquestionably an etiological factor in some cases. The etiology, especially from an histological point of view, is very interesting and is of importance in considering the correction of this defect.

Hereditary influences, by far the most frequent factor and the most important consideration, begin as a rule to assert themselves about the time of puberty, and from that time even up to middle age the deformity may increase. As age advances the increase is only apparent and is due to the disproportion arising between the nose and its facial environment, owing to the relatively more rapid shrinkage of the soft tissues of the face occurring at this period of life, while the firmer structures of the nose remain practically the same.

Viewing the development of this deformity from an anatomical and histological point of view, I am forced to conclude, from a study of the effect on the development of the nose of diseases and injuries which affect the growth of the septum, that the exaggerated, aquiline hooked nose is due to an inherent tendency on the part of the septum to extraordinary growth in its vertical diameter. It has long been my belief, a belief founded upon a close study of the dynamics of nasal development, that the growth of the septum is the chief factor in the development of the flattened nose of the infant into the more prominent organ of the adult. The pressure exerted by this structure during its period of growth is in an upward and forward direction, with little or no force horizontally in the direction of the tip. An exaggeration of these forces in the direction indicated produces the aquiline nose, and the relatively less pressure towards the tip leaves the latter on a lower level, producing a hook-like effect.

In considering the mechanics involved in the production of this deformity, we must remember that the vomer and the arch of the hard palate offer a point of unyielding resistance to the vertical force exerted in that direction by the growing septum; this force, therefore, must find expression in the direction of least resistance, and results in raising the dorsum of the nose to a higher level.

Is it possible to prevent the aquiline deformity? Is it feasible to remove the possibility of the development of this deformity by a free resection of the septum at the right time, thus anticipating the action of the offending forces in those hereditarily predisposed? This question presented itself to me most forcibly while I was studying the dynamics of nasal development and preparing the material for a paper on this subject which was published in the *Annals of Otology, Rhinology, and Laryngology* in December, 1914. Believing as I do even now that this subject, like matrimony, should be approached

discreetly, advisedly, solemnly, and in the fear of God, I hesitated even to mention the deductions I had made and which were strongly impressed upon my mind. I determined, however, to watch two patients, one 14 and the other 16 years of age, upon whom I had done free resections for deflected septa. Both of them were strongly predisposed by heredity to aquiline deformity, but as yet had shown no signs of its development. One of these patients I had under occasional observation for three years and the other for four years after the operation, and neither showed any signs of developing the deformity. I realize that this experience is merely suggestive and that it does not entitle either my views or my methods to acceptance, nor is it sufficiently convincing to induce me to advise the submucous operation solely as a preventive measure in those predisposed by heredity to this deformity. However, the idea is worthy of serious consideration, for it is founded, I believe, upon sound mechanical principles and a correct interpretation of the forces which enter into the development of a normal nose. As the operation involved is simple and if properly performed is never followed by bad results, and as the procedure is frequently necessary in order to relieve nasal obstruction, there is no reason why the submucous operation should not be tested out as a precautionary measure against the development of this deformity, and it is my intention to do so whenever the opportunity presents itself.

The traumatic variety of the aquiline deformity is not so common and is as a rule more irregular in its outline than the hereditary form. Apparently it is due not to an overgrowth of the septum but to a proliferative periostitis or perichondritis over the dorsum of the nose. This may result from one very severe injury, but it is more frequently due to repeated injuries such as are received by football players. In the case of the fullback on one of our famous football teams, recently operated upon by me, I found a growth of tissue of the consistency of cartilage and fully ¼ of an inch in thickness over the dorsum of the nose. This had to be removed before the correction could be made. In this instance the septum took no part in the production of the deformity, for it was crumpled up. The overgrowth of tissue was entirely extraneous to the nasal cavities, and was due to a proliferative periostitis or perichondritis.

Only yesterday there came to me a young woman, a Gentile, with no hereditary tendency to this deformity, who gives a history of having had a perfectly straight and satisfactory nose up to three years ago; shortly before this she had fallen and injured her nose very badly. She soon noticed a change in the contour of her nose; this has steadily increased, until now there is a pronounced aquiline deformity. In this instance the septum apparently took part in the process; this, however, is unusual in traumatic cases.

Treatment.—The only effective treatment for this deformity is operative. This is extremely satisfactory. No scar is left, as all of the work is done from within the nose. The strength of the nose is not impaired. In many instances it is necessary to shorten the tip and reduce the bulbous extremity of the nose. The entire operation, as a rule, is done at one sitting, and either local or general anesthesia may be employed. I have found no difficulty in doing the operation under novocaine and adrenalin, if a small dose of morphine and atropine is administered beforehand.

Instruments.—The following instruments were specially designed for this operation, and were made under my personal direction: A submucous knife; a longitudinally concavoconvex saw; a spatula-shaped knife having three sharp cutting edges; a curved rasp with specially designed teeth; modified Adams' forceps; copper splint for nose.

Operation.—After the proper antiseptic precautions have been observed, an incision is made through the mucous membrane of the roof of the left nasal cavity at a point corresponding to the interval between the upper and lower lateral cartilages. The spatula knife is then introduced and the tissues of the nose are elevated over the entire dorsum, care being taken to keep under the periosteum over the nasal bones. The saw is then introduced and the entire hump sawn off. This frequently leaves the dorsum of the nose flat, which is most undesirable; so I have devised a little instrument for removing the upper edge of the septum; the lateral walls of the nose can then be approximated at the apex by bending them inward by means of the Adams' forceps. This produces the rounded apex to the dorsum of the nose. There still remain, however, numerous little irregularities which must be smoothed down with the rasp; this instrument is most useful; the teeth are so arranged that the fragments of detritus are thrown toward the center, and clogging does not occur.

There are some cases which are not easily amenable to correction by means of the operation I have just described; I refer to those noses having very pronounced humps and broad, massive bases. To truncate the nasal cone under these circumstances would not produce a pleasing effect; so the following operation, which I regard as more difficult, but which I have found most satisfactory, should be performed: A high submucous operation on the septum should first be done. This should not include the upper edge of the septum which forms the keystone of the nasal arch.

The tissues over the sides of the nose are then elevated, and a wedge-shaped piece is removed from either nasal process of the superior maxilla. The dorsum of the nose is then forced down by means of the Adams' forceps, thus reducing the deformity.

When the nose is too long, which is frequently the case, it is shortened by removing a fan-shaped piece from the septum and pushing the tip of the nose up and sewing it in position. This last operation is done after the dorsal deformity has been corrected. After all of the blood and detritus have been removed from the sacs made by this extensive submucous and subcutaneous dissection, the nasal cavities are lightly packed with sterile vaseline gauze, prepared as I have previously described, and a well-fitting and properly padded copper splint applied; this splint remains on as a rule for four or five days or until healing is complete.

I have operated upon about fifty cases by the methods I have described and the results have been most satisfactory.

REMARKABLE VITALITY IN THE LARVA OF AN INSECT (*ALAUS OCULATUS*).

By R. W. SHUFELDT, M.D.,

WASHINGTON, D. C.

ENTOMOLOGISTS have long been familiar with the tenacity of life exhibited on the part of certain insects or their larvæ, and in the past many authors have published accounts having reference to it. It is a well known fact that such insects as wasps, for example, will sit up as though nothing had happened and preen themselves an hour or so after decapitation. Ants sometimes exhibit a similar disregard for the loss of their heads; and even such delicate creatures as butterflies furnish instances of this phenomenon in the insect world. Only a short time ago, the writer was arranging upon a spreading-board a series of butterflies he had captured, and among them was a fine male *Papilio turnus*—our Tiger Swallowtail. Being pressed for time, this specimen was held in the usual way—by the four wings shut up together over the back, while the entire body was given a bath of pure chloroform. Apparently, this instantly deprived it of life, and it was at once arranged with insect pins on the spreading-board. A couple of hours afterwards, this particular Papilio had not only survived the effects of the anæsthetic, but he had mustered the strength to pull out all the pins, including the one in the body which had held him in place on the spreader, and he was found on the floor, staggering along in an effort to escape.

However, here is a case that is far and away ahead of anything of the kind ever brought to the attention of the writer. Early in May, 1919, he was

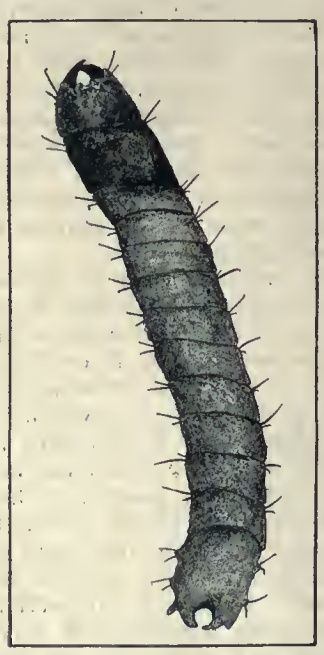

FIG. 1.—Larva of the Click Beetle; enlarged four times. From life, by the writer.

collecting forest insects near Dyke, Virginia, accompanied by his wife. Upon tearing the bark from a large, dead oak, various insects or their larvæ were exposed, being duly secured and consigned to the cyanide bottle as rapidly as possible. In turning over a bit of rotten wood, a dark yellow-colored larva, about three and a half cms. long, was exposed. It was very hard and shiny, its body being vertically compressed and composed of some twelve joints, the anterior one black, as was

FIG. 2.—The Click Beetle (*Alaus oculatus*); natural size. From life, by the writer.

the additional forward one, which bore the sharp, inwardly curved, needle-pointed, mandibular forceps. This specimen was picked up in the usual way—to be consigned, with the others, to the cyanide-jar; but the fellow fastened himself on the side of one of the collector's fingers with the above described jaws, holding on with the most remarkable strength and pertinacity. The blood flowed freely from the puncture, and no little pain accompanied the bite. By the aid of a pin, and with some difficulty, this vicious and slippery larva was compelled to let go its hold, whereupon it was put into a covered pill-box along with a lot of damp, rotten wood for further investigation. It remained in its close quarters all night. A day or so later it was dipped in pure formalin, and put aside with a number of beetles similarly treated, the latter being immediately killed by the bath. Not so, however, this yellow larva; so he was subsequently given a dip in 95 per cent. alcohol for fully a minute. This seemed to stiffen him out, and the entire lot was sent down, in a sealed glass vial, to Dr. E. A. Schwarz at the U. S. National Museum for identification. Dr. Schwarz very kindly returned them in the same receptacle in a few days, pronouncing the yellow larva to be one of our common Elaterid, the Eyed Click Beetle (*Alaus oculatus*). These specimens were then placed in a little tray, awaiting their turn to be pinned and placed in the collection, which task was begun the next morning. To the infinite surprise of the writer, the Click Beetle larva was as lively as the day it was captured! This appeared to be so unusual, that the specimen was removed to a small glass jar containing about an inch of damp, coarsely powdered and rotten wood, and in this it seemed to be perfectly at home. At the end of a week it presented no changes what-

ever—its form, color, and viciousness being the same as when it was captured. Thus it remained without any apparent alteration until the first part of July, 1919, when it was put into a cylindrical glass vial, seven and a half cms. high, with a diameter of one and a half cms. This was *tightly corked* with a sound cork, one and a half cms. thick. It is fair to presume that no fresh air could gain access to the interior of this vial, which was perfectly clean and transparent, admitting of a full observation of the behavior of the specimen within. For a while it remained quiet; but by next morning it had made up its mind to try to effect its escape, and consequently it attacked with its powerful jaws the edges of the inner surface of the cork. It was interesting to note the practical manner in which it cut into it. However, the task was a good one, and would have been well accomplished had he not been taken out about July 12, 1919, and returned to his old quarters in the jar containing the powdered, rotten wood, he having been in the sealed tube about 10 days without a change of air, and with no food or water. On the forenoon of the 10th of August, 1919, the specimen was as lively as the day it was captured, the only observable changes being a slight shrinkage in size, and a marked fading in color, it now being a pale, yellowish white. When placed on the table in front of the writer, it crawled actively away with the three pairs of legs on the leading segments of the body, viciously turning about if interfered with in any way. Being teased with an insect-pin, it seized the latter with its jaws, and held on to it with the most marked determination. For over three months this larva had had no water or other fluid to drink —in fact it has not been near any fluid since it was immersed in the formalin and the alcohol several months ago, as described above. On the morning of the 17th of July, 1919, the writer collected another very perfect specimen of this larva, and at once sealed it up in a glass tube of the same sort in which the first larva was kept. This specimen made no attempt to escape by cutting through the cork with its mandibles; it was kept without food or fresh air until the 4th of August, 1919, upon which date it died, having been in the tube 18 days under the conditions imposed.

This, of itself, is rather remarkable; and why it did not stand the test which the first specimen was subjected to would be extremely difficult to define. It may have been a much older individual, though nothing about it would lead one to suspect that that was the case. It was certainly much later in the season when it was collected, and it may have been suffering from some disease not distinguishable to the human eye.

These are the only specimens of the larvæ of *Alaus oculatus* that the writer has experimented with, and he believes that the matter merits further investigation. As this larva, so far as known, is not an enemy to any of our forest or shade trees, its destruction does not concern us; but there may be others, of different species, that are enemies of trees, in which case the above facts and information are likely to prove of some value.

Most elaterid larvæ are known as wire-worms, and have the appearance of the one here shown in Figure 1; they either live a subterranean life and feed upon the roots of grasses or other plants, or they live as did the one described above before capture. Few of the forms are predaceous. The drawings illustrating this article were made by the author, and are from specimens of the insects themselves. As this article goes to press, it may be stated that the first specimen described lived until the latter part of August, 1919, gradually drying up from the middle of that month, until it ceased to exist.

3356 Eighteenth Street.

Medicolegal Notes.

Exclusion from School on Account of Communicable Disease.—In order to prevent the spread of a communicable disease, trachoma, a North Dakota county board of health issued an order requiring school officers to deny admission to public schools to children who were affected with the disease or who were suspected of being affected, and who were not at the time under treatment. A survey was made by a representative of the Federal Government, which resulted in finding within the county 120 positive and 350 suspected cases of trachoma. The North Dakota Supreme Court held that the order of exclusion was reasonable. Where qualified physicians disagree upon the diagnosis of a diseased condition of particular persons, the health authorities and a school board, whose duty it is to execute the orders of the board of health, are justified in acting upon the opinion of their own competent experts. In such a case mandamus would not issue as a matter of right, but only in the exercise of a judicial discretion, and this discretion should not be exercised in a way that might result in needlessly exposing healthful children to a disease as serious as trachoma.—Martin v. Craig (N. Dak.) 173 N. E. 787.

Question Whether or Not Disease Was Chronic Held, on Evidence, for Jury.—In an action against a hospital association for breach of contract to render the plaintiff medical and surgical treatment and furnish hospital facilities, it appeared that in replying to the plaintiff's request for care and service the hospital virtually refused to treat her on the ground that her disease was chronic and not subject to treatment under the contract. The evidence introduced indicated that in 1910 the plaintiff suffered from prolapsus uteri, and that as a result of an operation she was completely cured of that trouble, and was in sound health when she became a party to the contract in 1911; that this condition continued for about two and a half years; that later, when the plaintiff did hard work or lifting, she had temporary prolapsus, but that her condition always became normal upon ceasing such work. The effect of the plaintiff's testimony was that she had frequent recurrences of the trouble at intervals, but that it was not permanent. It was held that whether the plaintiff's ailment was chronic was a question of fact for the jury, who were instructed, in substance, that the burden of proof was upon the plaintiff to show that she was not suffering from a chronic ailment.—Coffey v. Northwestern Hospital Assn., Oregon Supreme Court, 183 Pac. 762.

Purchase of Opium by Registered Physician for Personal Use.—The Federal District Court for the District of Montana holds that an indictment charging that the defendant, as a physician registered under the Harrison Narcotic Act, by means of the prescribed forms, obtained opium for his own personal use, did not charge an offense under section 2 of the act, which, to be constitutional, must be construed as in aid of the revenue feature of the act, viz., to create and safeguard revenue. "How the purchase herein alleged," the court said, "could in any wise affect the revenue is inconceivable. Nothing in section 2 forbids purchases for any lawful use. Among such may be purchase to destroy, or to absorb the supply, or to prevent purchase by others, or to obstruct illegal traffic, all of which are lawful purposes, and none of which are within section 2, even as purchase for personal use is not."—United States v. Parsons, 261 Fed. 223.

EXPERIMENTAL PNEUMONIA.

ALTHOUGH pneumonia is one of the most frequent of the infectious diseases as we meet them under ordinary circumstances, and has been especially prevalent during the past two years, and although it has been made the subject of much careful study, our exact information concerning it is still very limited. In spite of the fact that the causative organism is well known the immunological aspects of lobar pneumonia are yet obscure. Although the pathological changes that occur in the organs during the course of the disease have long been recognized and studied, diagnosis and prognosis are still uncertain. One reason for this state of affairs is that until recently it has been impossible to produce in animals a pneumonia that resembles clinical lobar pneumonia as it occurs in man. During the past winter Blake and Cecil carried out an intensive study of the disease and devised a means of producing it at will in monkeys. The observations of these experimental infections have furnished a large amount of data which the authors have assembled in a series of papers of which the first two have recently appeared (*Jour. Exper. Med.*, 1920, xxxi, 403 and 445). It is worth while to present their findings briefly. For the complete presentation of their evidence and the discussion of their conclusions it will be necessary, and profitable, to read the original papers.

In the first place they have been able to produce lobar pneumonia in monkeys consistently by the intratracheal injection of small doses of a broth culture of the pneumococcus, irrespective of its type. The disease thus produced is identical both clinically and pathologically, with lobar pneumonia as it occurs in man. Neither subcutaneous nor intravenous injection resulted in pneumonia though several of the animals thus treated died with pneumococcus bacteriemia. The throats of several monkeys were sprayed with broth cultures of pneumococci but none of these animals developed pneumonia although these organisms could be identified in the sputum for at least a month. Nevertheless, at least one animal developed pneumonia after having been confined in a cage with other animals suffering with the disease. It would seem then that the mere presence of a virulent strain of this organism in the upper respiratory tract is not enough to produce a pneumonia even though it must be through that tract that infection normally occurs. When virulent organisms gets a foothold beyond the larynx, then infection almost surely follows.

Immediately after the injection there is a sharp rise in the number of leucocytes in the blood and pneumococci may be obtained by blood culture before the appearance of any clinical evidence of infection. After this initial leucocytosis, which is accompanied by a polynucleosis, there is often a fall in the number of leucocytes, the lowest point corresponding to that at which the organisms are most numerous in the blood culture. With the onset of the crisis and the approach of recovery, the leucocytes again increase. In severe and prolonged infections there is evidence that most of the polynuclears are immature and in the more severe cases there may be complete exhaustion of the bone marrow. In rare instances when the infection is especially severe there may be but little leucocytic reaction. Occasionally there are nucleated red cells and myelocytes in the blood stream.

The evidence that pneumonia is bronchogenic rather than hematogenic is confirmed by the evidence the authors obtained in study of sections of lungs removed at autopsy. It was found that the initial lesions were an invasion of the interstitial framework of the lung with an accompanying involvement of the lymphatic system. The organisms soon get into the blood stream by way of the lymphatics and reach the pleura by way of the perivascular, peribronchial, and septal interstitial tissue. Consolidation appears first at the hilum and gradually spreads out from there until the entire lobe is involved. The complications found were similar to those seen in man—empyema, pericarditis, and pleurisy. Resolution was frequently accompanied by a varying degree of organization of the grosser framework of the lung, while in several instances there was found a definite organizing pneumonia as in one animal which died on the thirty-seventh day of his disease.

Studies of this type comprise our chief source of exact information which is necessary in the rational treatment of disease. Many of their observations on animals can readily be repeated on man and should prove a vigorous stimulant to that form of investigation. The remaining papers of this series will be awaited with interest.

MENSTRUATION AND LACTATION.

FAR from being a rarity, menstruation in nursing women is a fairly frequent phenomenon. Out of a total of one hundred wet-nurses, about forty-five have their menses during lactation, and in the majority of them menstruation returns between the third and sixth month following delivery.

Those having their menstruation are usually the ones that appear to be in robust health, and the few who enjoy only a mediocre health are in a decided minority. The nurslings of the latter are more subject to the usual affections of infancy. In a good nurse the menses are about as abundant, last about as long, and have the same regularity as before fecundation.

The composition of the milk of a menstruating nurse should be considered at two different epochs —during the intermenstrual period and during the menstruation. The intercalary milk is absolutely like the milk before the advent of the menstrual function. According to the results obtained from analyses conducted by Gillet, the menstrual milk, instead of being more serous as most observers maintain, is, on the contrary, of higher specific gravity and richer in nutritive principles; the quantity of butter increases, that of sugar diminishes; the decrease in salts is insignificant. The return of the menstruation in a good nurse produces no appreciable effect on the health of the infant, who continues to gain weight after the normal standard; at least this has been the experience of many observers. The loss of salts is so slight that it can exercise no influence in the production of infantile rickets. There is no relation of cause and effect between menstruation in the nurse and convulsions in the nursling. Out of a total of one hundred infants suckled by menstruating women, 17.9 per cent. were slightly indisposed during the menstrual period; but before this should be incriminated as the cause, pathological factors, such as dentition, must be eliminated. The milk being richer in nutritive principles during menstruation, the colic and diarrhea may very likely be due to indigestion, especially in greedy infants and when the time of nursing is not regulated.

Given the fact that the return of the menstrual function appears to occur especially in the more robust nurses enjoying flourishing health, it may well be asked if it would not be preferable, in the interest of the infant, to choose a wet-nurse in whom the menstrual function has returned. Contrary to the general belief, the majority of nursing mothers who become pregnant should continue lactation, which will have no disastrous effect upon the nursling; but also it must not be forgotten that simultaneous pregnancy and lactation are for the mother two serious sources of fatigue; therefore the physician must use his judgment in advising weaning.

Is Influenza-Pneumonia Contagious?

The above question is asked by Motzfeldt in the *Norsk Magazin for Laegevidenskaben* for February, 1920, lxxxi, 2. This malady, if such it can be termed, was known to Sydenham, who pronounced it quite distinct from ordinary pneumonia, while during the period 1830-1837 there was much discussion as to the autonomy of influenza-pneumonia in France. During the pandemic of 1889-90 bacteriology was available and appeared to show that grippe pneumonia was due to the exciters of ordinary pneumonia, while influenza *per se* was due to Pfeiffer's bacillus. There was some attempt to show that the latter could itself cause the pneumonia of influenza (Leichtenstern, Wassermann). But the percentage of these patients to develop the complication was often very small. The author now passes to epidemic and contagious pneumonia as an autonomous malady. As early as 1867 numerous Scandinavian physicians believed that pneumonia was sometimes transmissible. The most recent laboratory and clinical work has led to the isolation of cases of pneumonia and the obligation of reporting all cases, without reference to epidemic incidence of influenza. Influenza-pneumonia has been recently pronounced an especially contagious form of the disease. This does not mean merely that the patient communicates influenza to others, but that those exposed may at once develop primary pneumonia. The author sent out a questionnaire to obtain first hand data. It appeared that in 33 per cent. of smitten families during the pandemic more than one case of pneumonia appeared. Of 174 influenza families comprising 858 members, 79 of the latter developed pneumonia, or 9 per cent. of all exposed. Of the 858 members 409 developed influenza, and of the latter, 79, as stated, developed pneumonia, or 19 per cent. of all infected.

Serotherapy of Typhoid Fever.

A TRUE serotherapy of typhoid fever, not to be confounded with a vaccine or proteinic therapy, is making headway in France according to an article by Rodet and Bonnamour in *La Presse Médicale* for January 31, 1920, xxviii, 9. Originally begun in 1907, it has slowly undergone an evolution until it may be accepted as a dependable resource. The authors have already published a series of 127 cases and since then the total has been increased to 240. The gross mortality in the first series was 11 per cent., but in a certain number of cases death was plainly due to some factor which could not have been reached by a specific serum. Just as in diphtheria and tetanus we deduct these septic cases and others due to associated affections, so in typhoid fever we may take the same liberty and this will reduce the death rate to 5 per cent. from the typhoid bacillus or its toxin. Unfortunately the second series of cases was vitiated because coinciding in part with the influenza pandemic, and the mortality instead of being lower as was anticipated was considerably higher. The total mortality for the two series from the specific cause went as high as 11 per cent. In the second series typhoid and grippe cases were sometimes confounded and hence the typhoid patients did not receive the best treatment, and in other cases there was probably a symbiosis as shown by the fact that typhoid subjects had complications which rather suggested influenza. The authors, therefore, were tempted not to publish the second series, but decided to give it for what it might be worth. But they believe in the future of the serum because it modifies the temperature curve in a specific manner and attenuates the toxic phenomena so markedly that in some cases one may speak of a veritable detoxication. Again

the serum gives results at any stage of the disease and not merely at the outset. The serum is so bland that no disturbances have been seen and hence there are no contraindications.

Uniovular Twins.

Uniovular, homologous, or monozygotic twins have always been objects of universal interest, but not much appears to be known of their intimate nature or genesis. They are always of the same sex and their frequency in comparison with ordinary twins is placed at about 7 to 1, although this is subject to revision, and we only know for certain that they are considerably less common than biovular twins. In the *Annales de gynécologie et d'obstetrique* for January, 1920, xiii, 12, Deluca and Widakowice of Buenos Aires publish a paper on the origin of these twins. The authors anticipate by the statement that thus far the hypothesis of Broman is the most plausible, he holding that they originate either from the conjunction of a spermatozoon with two tails—or two pairs of centrosomes—with an ovum having either a single or double nucleus. The various other hypotheses are enumerated and the authors add their personal investigations in connection with the incidence of bicaudate spermatozoa. Since 1881 it has been known that spermatozoa with a double centrosome are more common than usual in syphilitics. In the normal subject Broman estimated the frequency as 1 or 2 per 1000. The authors having examined many South Americans make this frequency about 6 to 1000. A study of average syphilitics gives a frequency of 13 to 1000 and of hereditary syphilitics as 32 to 72 per 1000. Spermatozoa with three or four tails are occasionally seen, but are excessively rare, although much less so in syphilitics. It is well established that uniovular twins show a decided tendency to appear in the progeny of syphilitics, so that Broman's hypothesis appears the more plausible.

Seniculture.

A writer in *Le Caducée* for March 1, 1920, xx, 5, calls attention to the recently published work by Professor Lacassaigne with the suggestive title, "Green Old Age." The author is eminent as a hygienist and the reviewer makes use in this connection of the neologism of "seniculture," as the cult of keeping old age green and making green old age possible. The term is, of course, cognate with puericulture, which is at present used chiefly in the sense of the prenatal care of the next generation. As puericulture is preeminently a matter for good legislation without which it cannot exist, so the author maintains that seniculture must be rendered real by the enactment of laws. Before we have laws we still have to accumulate and digest all possible facts about old age, not only physical but psychical. The next step is to formulate a sound hygiene of old age. The cult requires that the Minister of Public Health recognize it in the same way that he recognizes puericulture. The reviewer says that a movement of this sort might be construed as a tribute of gratitude to the grand old man Foch for his contribution to civilization. Naturally private as well as public movements should be initiated to foster this movement and societies of seniculture should be established. The reviewer does not descend to the concrete in his short outline of Lacassaigne's book beyond a mention of printed instructions or tracts to be given out to the old men of the nation. Every State or province should have its society for seniculture.

News of the Week.

Missouri Surgeons to Organize a State Clinical Congress.—At a meeting of Missouri surgeons, held in St. Louis on May 2, a Missouri section of the Clinical Congress of the American College of Surgeons was organized. An Executive Committee was appointed to arrange plans for the first meeting which will probably be held in the early fall. This committee is composed of Dr. Harvey G. Mudd of St. Louis, Dr. William H. Luedde of St. Louis, and Dr. Jabez N. Jackson of Kansas City.

American Officers of the Great War.—The aim of this Society of men who formed the officer class in the Army, Navy, or Marine Corps, during the war is to take such united action as shall be advisable or necessary in protection of the interests they may have in common. There are already more than 17,000 members. A New York Chapter is being formed, Dr. Howard Lilienthal, of 52 East Eighty-second Street, being chairman of the committee to interest the medical profession. Application blanks for membership may be obtained from Dr. Lilienthal.

New Home for Medical Society.—The corner-stone of the new building of the Medical Society of the District of Columbia, at 1718 M Street, Washington, was laid on the afternoon of May 6. Dr. C. W. Richardson presided at the ceremonies. The corner-stone was laid by Dr. Francis R. Hagner, president of the society. Addresses were made by other officers and trustees.

Campaign against Cancer.—The American Society for the Control of Cancer held a special meeting at the New York Academy of Medicine on May 13, at which Dr. Harvey Gaylord of Buffalo spoke on the "Less Familiar Problems of Cancer," and Dr. Howard Lilienthal discussed the subject of "Cancer from the Standpoint of the Clinical Surgeon." This meeting was the opening event of the campaign against cancer that is to be carried on in this city during the last two weeks in May, when a large number of meetings will be held in different parts of the city. Dr. Frederick T. van Beuren is director of the campaign. Twenty-five physicians have agreed to deliver addresses to lay audiences during the campaign.

Bronx Hospital Opened.—The Bronx Hospital, at 169th Street and Fulton Avenue, was formally opened with exercises on the afternoon of May 9. Among the speakers were Hon. George McAneny, Dr. John W. Brannan, and Dr. A. A. Berg. Dr Emil Juper is superintendent of the institution, and Dr. A. A. Berg and Dr. Martin Rehling chief surgeons.

Oppose Chiropractor Bill.—At a hearing before

Governor Smith, on May 13, on a bill providing for licensing chiropractors in the State of New York, Dr. Augustus S. Downing, Deputy State Commissioner of Education, and Dr. Hermann M. Biggs strongly opposed the bill, holding that it would be a serious blow against all public health effort. Representatives of the Health Officers' Associations, the State Charities Aid Association, the New York City Department of Health, and the New York Academy of Medicine also voiced their opposition.

Florence Nightingale Centenary.—A Florence Nightingale Centenary Dinner was held last week at the Hotel Biltmore, New York, at which a movement to increase the nursing forces of New York City was launched. Among the speakers of the evening were Surgeon General Merritte W. Ireland, Dr. Livingston Farrand, P. Whitwell Wilson, a member of the British Parliament, Homer Folks, and Miss Annie E. Goodrich. Announcement was made that Governor Smith, on the one hundredth anniversary of the birth of Miss Nightingale, would sign the Nurses' Practice Bill, designating and licensing trained nurses, and making it unlawful for anyone to practise nursing before graduation from a nursing institution.

Intensive Course in Syphilis.—The Rochester Health Bureau announces an intensive course of one week in syphilis, which will be held at the State Hospital and the general hospitals and dispensaries. The course includes: (1) The history and municipal control of syphilis; (2) Clinical lectures, demonstrations, and participation in dark field work, the taking of Wassermann reactions, the preparation of arsphenamine and the technique of its administration, methods of giving mercury, spinal puncture, and the cytology and chemistry of the spinal fluid. The course, which is free, will be given twice. The first course will be given from June 14 to 19, inclusive, and the second from June 21 to 26, inclusive. Applications must be in by June 12 and 18, and must be addressed to the Health Bureau, Chestnut and James Sts., Rochester, N. Y.

Vacancies in United States Public Health Service and Panama Service.—The United States Civil Service Commission announces the following examinations: A vacancy in the Panama Canal Service, for which examinations will be held on July 7 and Sept. 6, 1920. Applicants must have graduated from a recognized medical school whose graduates are eligible for commission in the United States Army, and must have had at least one year's post-graduate hospital experience. The examination is open to men and women. The position pays a salary of $225 a month with increases. Another examination is announced to fill the position of physician in the Indian Service, acting assistant surgeon in the Public Health Service, surgeon in the Coast and Geodetic Survey, and positions requiring similar qualifications. The entrance salary in the Indian Service ranges from $1,000 to $1,200; in the Public Health Service, from $480 for part time to $2,400 or $3,000 a year for full time; Coast and Geodetic Survey, $1,020 per year, with an allowance for subsistence at $1 per diem while on shipboard. These positions are open to both men and women. Competitors will not be required to report to any place for examination, but will be rated on their physical ability, education, training, and experience. There is also a vacancy for a bacteriologist at St. Elizabeth's Hospital, Washington, D. C., at $2,500 a year, with temporary increase granted by Congress of $20 a month. For this vacancy male eligibles are desired, though vacancies requiring similar qualifications, will be filled from this examination, at this or higher or lower salaries, for which women may be eligible. Competitors will not be required to report at any place, but will be rated on their physical ability, education, training and experience. Applicants for any of these positions should apply at once for Form 1312, stating the title of the examination desired. All applications should be mailed to the Civil Service Commission, Washington, D. C., except those for the position of bacteriologist, which should be sent to the Secretary of the Fourth Civil Service District, Eighth and E Sts., N.W., Washington, D.C.

Prohibition That Does Not Prohibit.—A few weeks since the report went out that the alcoholic ward at Bellevue Hospital was to be closed for lack of patients, that the Municipal Lodging House was practically vacant, and that the number of "alcoholics" in the city hospitals had been diminished to from one-fifth to one-third their former number. Bird S. Coler, Commissioner of Public Welfare, now asserts that the wards are not only not empty, but that the number of patients is increasing and that many of these persons are in a serious condition owing to the fact that they are getting much worse liquor than when the traffic was regulated. He threatens to send out inspectors if there is no better enforcement of the prohibition within the next thirty days. It is notorious that any one wanting a drink of whiskey in this city can get it without difficulty if he has the price; but a sick person who may need alcohol to save his life is allowed only one pint in the course of ten days, or an ounce and a half a day.

Dr. Lawrence F. Flick of Philadelphia has been awarded the Laetare Medal of Notre Dame University in recognition of his work in medicine and Catholic history.

Dr. Louis Pearce of the Rockefeller Institute for Medical Research has sailed for England *en route* to the Belgian Congo for the purpose of studying the chemotherapy of African sleeping sickness.

Colonel James D. Heysinger of Portland, Me., has received from the French Government the decoration of the Order of University Palms, which carries with it membership in the French Academy.

Dr. William W. Blackman of Brooklyn has been appointed to the newly created office of president of the New York Homeopathic Medical College and Flower Hospital.

Dr. Reid Hunt of Harvard was elected president of the United States Pharmacopeial convention, on May 12, to succeed Dr. Harvey W. Wiley.

Dr. Stanley H. Osborne, formerly epidemiologist of the Massachusetts State Department of Health, has been appointed director of the Division of Preventable Diseases in the Connecticut State Department of Health.

Dr. John A. Ferguson of Brooklyn has been appointed a member of the Board of Education of New York City.

Dr. William H. Dieffenbach of New York City has removed to 50 Central Park West.

Sir Archibald E. Garrod, K.C.M.G., M.D., F.R.S., has been appointed to the Regius Chair of Medicine at Oxford to succeed Sir William Osler.

Births in Registration Area.—According to statistics just completed by the Census Bureau, births in the registration area of the United States, which covers about 53 per cent. of the country's estimated population, during the year 1918, exceeded deaths by 34.4 per cent. There was a total of 1,363,649 births in 1918, which was a small decrease compared to 1917. Of every 100 infants born in 1918, ten died before reaching the age of one year, a fractional decrease over 1917. The mortality rate among male infants was 23 per cent. greater than among females. The birth of 15,342 pairs of twins and 147 sets of triplets was reported.

Want Woman on Staff of Isolation Hospital.—At the annual meeting of the Medical Women's National Association in New Orleans, during the last week in April, this organization advocated the appointment of a woman physician on the staff of the Isolation Hospital in New Orleans.

Institutions for Children Show Lower Mortality and Morbidity Rates.—The New York Department of Health presents an analysis of medical work during 1919, under the supervision of the Division of Institutional Inspection, showing that advances have been made in the institutional care of children. During the past year, the number of deaths in homes for children was reduced approximately 44.3 per cent. The incidence of communicable diseases showed a decrease of about 31 per cent. Non-communicable diseases diminished 4.5 per cent., while the death rate was reduced over 14 per cent.

Medical Society Elections.—THE AMERICAN MEDICAL EDITORS' ASSOCIATION, at its annual meeting held in New Orleans April 26 and 27, 1920, elected the following officers for the ensuing year: *President,* Dr. H. S. Baketel, New York; *First Vice-President,* Dr. Frank Lewis, New York; *Second Vice-President,* Dr. F. H. McMechan, Avon Lake, Ohio; *Secretary and Treasurer,* Dr. Joseph MacDonald, Jr., New York.

THE AMERICAN ASSOCIATION OF ANESTHETISTS, at its annual meeting held in New Orleans April 26 and 27 elected the following officers for the ensuing year: *President,* Dr. Joseph F. Lumbard, New York; *First Vice-President,* Dr. F. L. Richardson, Boston; *Second Vice-President,* Dr. Eleanor Seymour, Los Angeles; *Secretary,* Dr. F. H. McMechan, Avon Lake, Ohio.

THE PLYMOUTH DISTRICT MEDICAL SOCIETY, at its annual meeting held at Brockton, Mass., April 15, 1920, elected the following officers for the ensuing year: *President,* Dr. Francis J. Hanley, Brockton; *Vice-President,* Dr. Richard B. Rand of North Abington; *Secretary-Treasurer,* Dr. Wallace C. Keith, Brockton.

THE NORTH CAROLINA HEALTH ASSOCIATION, at its annual session held in Charlotte, April 19, 1920, elected the following officers for the ensuing year: *President,* Dr. R. L. Carleton, Winston-Salem; *Vice-President,* Dr. L. J. Smith of Wilmington; *Secretary-Treasurer,* Dr. G. M. Cooper, Raleigh.

THE NORTH CAROLINA HOSPITAL ASSOCIATION, also in annual session in Charlotte April 19, 1920, elected the following officers for the ensuing year: *President,* Dr. J. M. Parrott, Kingston; *First Vice-President,* Dr. J. R. Alexander, Charlotte; *Second Vice-President,* Dr. P. R. McFadden, Concord; *Third Vice-President,* Miss Gilbert Muse, High Point; *Secretary and Treasurer,* Dr. John Q. Myers, Charlotte.

THE NORTH CAROLINA MEDICAL SOCIETY, which met in Charlotte April 20, elected the following physicians to the State Board of Medical Examiners for the next six years: Dr. L. A. Crowell, Lincolnton; Dr. L. L. Glenn, Gastonia; Dr. J. B. Murphy, Wilmington; Dr. C. A Shore, Raleigh; Dr. W. M. Jones, Greensboro; Dr W. P. Holt, Duke, and Dr. K. P. B. Bonner, Morehead City.

THE BERKSHIRE DISTRICT MEDICAL SOCIETY, at its annual meeting in Springfield, Mass., April 30, elected the following officers for the ensuing year: *President,* Dr. Ayres P. Merrill; *Vice-President,* Dr. George P. Hunt; *Secretary,* Dr. O. L. Bartlett; *Treasurer,* Dr. Charles T. Leslie.

Obituary Notes.—Dr. H. HOLBROOK CURTIS died at his residence in New York city of diabetes with complications, on May 14, aged 63 years. Dr. Curtis was born in this city on December 15, 1856, the son of Judge William Edmond Curtis. He was graduated from Yale, in 1877, and from the medical school of that university, in 1880, after which he spent several years studying in the universities of Vienna and Paris. Dr. Curtis was a member of the American Laryngological, Rhinological, and Otological Society and a former president of the society; a member of the American Medical Association, and of the New York Academy of Medicine; a Fellow of the Royal Medical Society of England, and a Fellow of the American College of Surgeons. He was visiting surgeon to the New York Nose, Throat and Lung Hospital, consulting otologist to the Nassau County Hospital, consulting laryngologist to the Minturn Scarlet Fever and Diphtheria Hospital. He was also vice-president of the American Social Science Association and Secretary of the National Institute of Social Sciences. For many years, until his health began to fail, Dr. Curtis was a frequent contributor to the medical literature in his special field.

Dr. SAMUEL C. HELMICK, a graduate of the Miami Medical College, Cincinnati, Ohio, in 1871, died from heart disease at his home in Commercial Point, Ohio, April 28, aged 71 years.

Dr. JOHN C. DACOSTA, JR., died at Philadelphia on April 26 at the age of 48 years as a result of injuries received in an automobile accident. He was graduated from Jefferson Medical College in the class of 1893. He served as first lieutenant in the United States Army during the Spanish-American War and he was for a time Associate Professor of Medicine in Jefferson College, Assistant Physician to Jefferson Hospital, Consulting Physician to the Northwestern Hospital, and Hematologist to the German Hospital. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, the Pathological So-

ciety of Philadelphia, and the American Medical Association, and a Fellow of the College of Physicians of Philadelphia. He was the author of several medical works, including a treatise on Physical Diagnosis, the fourth edition of which was recently published.

Dr. EWING JORDAN, librarian of the University of Pennsylvania, died at Philadelphia on April 28 at the age of 63 years. He was graduated from the medical department of the university in the class of 1871 and he served for a time as first assistant physician to the Pennsylvania State Hospital for the Insane at Norristown.

DUCTLESS GLAND PATHOLOGY IN U. S. SOLDIERS DURING THE EUROPEAN WAR.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Being interested in material on diseases of the glands of internal secretion in U. S. soldiers in our army camps and at the front during the European War, I should feel much indebted to any physician who has served as a medical officer in the Army during the war who might be able to supply me with any information in regard to this matter, particularly statistical relations, semeiology, the incidence of these diseases in drafted men and in enlisted men who were subsequently on duty, and the measures taken in dealing with such cases. Any help I may receive in this matter will be highly appreciated and acknowledged.

JAMES ROBB CHURCH,
Colonel, Medical Corps, U. S. Army.

WASHINGTON, D. C.

RETURNING TO SENSIBLE THERAPEUTICS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It is a source of gratification to note in our exchanges the increasing number of communications from medical men who are giving us their experiences in the treatment of various affections successfully with certain drugs or favorite combinations that they have used during many years until now they feel very sure and confident of the results expected. In these days of new and accepted theories, we may have gained something worth holding, but it is very certain that we have drifted far away from more good remedies than we have found in the substitutes that we are trying to push into recognition.

As practitioners we too often lose sight of the fact that the human machine is a most sensitive and watchful organization, and one that is so responsive to varied influences that it is difficult to determine at all times just which of our agencies produced the good or bad results. For this reason we should know that the theoretical formula from the laboratory, and this, that or the other specific, may be good, but can never be depended upon as a cureall. Many physical and mental conditions must be taken into consideration when administering remedies, and these remedies will be affected in their action by influences operating on the patient.

Very often we have heard practitioners extolling the merits of certain remedies and declaring how they seldom or never failed them in certain diseases. We often see the same thing in our medical journals from honest practitioners who believe in what they say; and yet we frequently have felt at first that they were deceived in their observations or were over-coloring things in their enthusiasm. But when we have taken a broader and more liberal view, we have concluded that the doctor possibly gave his patient, along with the drug, a portion of his own faith and hope and so directed his mind in the proper channel that just what was expected of it was realized fully. I should dislike to be ridiculed as a faith-healer, or a Christian Scientist, for I am a very big believer in drug action when properly prescribed, but I am going to run the risk and tell my readers that I have very little faith in drug action upon any human being who does not think my remedies are going to do him any good. "Thy faith hath made thee whole" is an expression that we could have honestly quoted to many of our patients after the administration of many and sundry remedies, and it is one of the best adjuvants we have to combine with any drug we may administer. But we are not talking about faith alone as a remedy, but of the actual faith that the experienced doctor has in articles of the materia medica, based upon his sufficient experience that amounts to actual knowledge.

It looks to us like a return to reason and sound therapy, when we see our journals carrying articles from such splendid and experienced practitioners as Dr. Beverley Robinson of New York, in which he introduces our old friends mutton suet with benzoin, epsom salts and glycerine locally, and pinches of cubebs for sore throat, with local applications of tr. iron and glycerine. W. R. D. Blackwood of Philadelphia is another man who can take a few common remedies and do more with them than any man I ever knew. It is because he has learned by experience what he can do with drugs when using them as indicated. He has faith in his drugs and in himself, and he knows what he can do. W T. Marrs of Peoria, Ill., is also a man who can think and observe and he has common sense enough to be guided by his experience. He is not ashamed of using a little spts. turpentine, camphorated oil, castor oil, glycerine or sage tea, and he is psychologist enough to make almost any combination work. He is the author of "Confessions of a Neurasthenic" and he can take these "nerves" cases at any angle and knock the spots out of them by simply looking them fiercely in the eye, and slipping them an assafoetida ball on the sly. A. J. Jameson, M. D., of Sentinel Butte, N. Dakota, has an excellent article along these same lines in the *Medical Summary*, of Philadelphia, in which he tells us so many things we can do with echinacea, and mentions his successes in treating infections and preventing same. These physicians and others like them are successful in the practice of medicine and they are drug healers of the highest order, and they are students of human nature, and sympathetic psychologists; and are men who think and observe and attach importance to their experiences. We have been led to make these comments because we feel that we have all strayed after new things and im-

provements and have left too many good and tried remedies behind until they are forgotten, and as many know we have become to an extent tacit, if not active, acknowledgers of therapeutic nihilism—a fatal attitude toward any step of progress in the healing art.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, April 30, 1920.

Criticisms of Panel Practice.—A good deal of discontent prevails among panel practitioners as to the working of medical practice under the amended insurance act. One practitioner has voiced his grievances in the law press, reference to which is made in the *Medical Press* of April 26, 1920. According to the experience of the writer, 5 per cent. of his panel patients had no attendance, 3.5 per cent., 100 or more attendances, and the whole list averaged 12 attendances per annum, while his services were paid for at the rate of sevenpence per attendance. At the rate of 33 prescriptions weighing one ounce, he found that in one year his prescriptions in weight amounted to 448 lbs. He states that some patients are of the opinion that the doctor's fee of one penny and a half penny, equivalent to three cents a week, savors too much of charity, and distrust the quality of the drugs supplied at two shillings (50 cents) per head per year inclusive of the druggist's fee. The result is that they become the private patients of another medical man, as their own panel doctor refuses to attend them as private patients. He denies that the average practitioner is financially better off since the act came into force. "It is surprising," he adds, "but the fact is that the wives and children do not seek medical aid more frequently than before the act, although many wives are now on the panel." The act indeed, seems to be open to criticism on several counts and it is more or less obvious that it requires further and considerable amendment.

Some of the Work of the International Health Conference.—During the international conference which sat at the British Ministry of Health for several hours of each day of the week ending April 17, some important points in connection with the health of the world were discussed and considered. As Parliamentary Secretary to the Ministry of Health Viscount Astor presided over the sittings of the conference, and on April 17, discussed with a newspaper representative some of the developments anticipated as an outcome of the conference. Referring to the work which had already been done, he said that the League of Nations recognized among other things that the Signatory Powers should interest themselves in matters affecting the health and welfare of their peoples.

The war had proved that all the countries of the world are interdependent; that modern communications had closely united all parts of the globe; that particularly there is a constant and rapid movement by rail and ship of people from country to country which facilitates the spread of epidemic diseases. Corporate bodies, as nations are, were recognizing that the individual obligation by which man was to be his brother's keeper and concern himself in the welfare of his brother applied to countries also. The decision of the League of Nations to cooperate in matters affecting public welfare was, he said, of the utmost importance in the progressive development of civilization. Early this year the Council of the League of Nations asked Dr. Addison, as Minister of Health, and in recognition of the fact that the United Kingdom was the first country to establish a specific Ministry of Health, to summon a conference and prepare proposals for the establishment of an international health organization. The conference was attended by representatives of France, Italy, Japan, the United States, and Great Britain. Belgian and Brazilian representatives were unfortunately prevented from attending at the last moment. In addition to these delegates, the League of International Red Cross Societies, the International Labor Bureau, and the Office Internationale d'Hygiène Publique were represented. Viscount Astor declared that the results of the deliberations exceeded all anticipations in the rapidity with which progress has been made and the proposals of an international health organization agreed to.

Briefly the proposals which it is intended to submit to the Council are: (1) That there should be an executive with a bureau and staff at the seat of the League. (2) That the Office Internationale in Paris, which has done so much in the past, should form a part of the organization; and as such the Office have expressed their desire to advise on such technical matters as might be referred to them. (3) That means should be found for cooperation between the new organization and the already established voluntary League of Red Cross Societies and the International Labor Bureau. In addition to working out the permanent structure, the conference has cooperated in advising on such measures as are immediately feasible in combating typhus in Poland and preventing its spread throughout Europe. That country is without sufficient means to establish any satisfactory barrier against the westward spread of the disease. Not only is there difficulty owing to the indeterminate state of Poland's eastern boundaries but there are difficulties also arising from lack of medical personnel, sanitary stores, and money. The delegates to the conference were as follows: France, M. Brisac, M. Leon Bernard, M. Boujard, M. Thiebault; Great Britain, Dr. G. S. Buchanan, C.B., Dr. Steegmann, Sir George Newman, K.C.B.; Italy, Dr. Lutrario, Dr. Bruno Fornaciari, Dr. Druetti; Japan, Dr. Yoneji Miyagawa, Mr. Kakichi Kawarata; America, Surgeon General Rupert Blue; League of Red Cross Societies, Colonel R. P. Strong, U. S. A.; Office Internationale d'Hygiène Publique, Dr. Potterin; Secretaries Dame Rachel Crowdy (League of Nations), Mr. L. G. Brock, Ministry of Health, Polish Ministry of Health, Dr. Chodzko.

Honor for Sir James Barr.—Sir James Barr, the well known Liverpool physician, has been appointed a Knight of Grace to the Order of the Hospital of St. John of Jerusalem in England.

3. The Technique of Lumbar Puncture.—Lawson G. Lowrey emphasizes certain points in the technique of lumbar puncture which, if observed, made the procedure a simple one. One of the most important points in satisfactory technique is that the needle shall be sharp, since with a sharp needle there is much less probability of excessive pain to the patient. The site of election for lumbar puncture is between the third and fourt lumbar vertebræ, this space being usually the widest. In children one must remember that the spinal cord extends to a lower point than it does in the adult. The third lumbar space is as a rule on a level with the crest of the ilium. This constitutes a useful guide in fat people. One must be careful to find the midline and to allow for spinal curvature if it exists. With the index and middle fingers of the left hand the operator locates the point at which he wishes to do the puncture. With the elbow raised these two fingers are applied to the midline from the left side of the patient. Having found with the middle finger the spinous process below which we wish to insert the needle, the index finger is then pulled downward on the spinous process of the next vertebra, thus rendering the skin tight and leaving a space between the two fingers, corresponding to the intervertebral space into which the needle is thrust. Most of the difficulties in puncture, which are not to be explained by lack of cooperation on the part of the patient, are due to the failure of the operator properly to direct his puncture. Having found the proper place, the needle is quickly thrust through the skin, and then further progress may be made more slowly. Pain in the lumbar region comes: (1) when the skin is pierced; (2) if the periosteum is touched; (3) referred pains occur if bundles of nerves are struck. Care must be taken that the needle goes in straight and not to one side. If it goes in at one side it should be withdrawn and redirected. Care must be taken not to overrun and go into the bone or intevertebral disc at the front of the canal. In many instances it has been found that twisting the needle without varying its depth of introduction assists in the flow, though it is not clear why this is so. One should not withdraw more than 10 c.c. of fluid, except in cases which are to be treated. It is very rare indeed for a paretic or other case of neurosyphilis to suffer any discomfort after lumbar puncture. Patients with normal meninges, however, often have headache and sometimes nausea and vomiting.

8. Diabetes in Association with Toxic Goiter. J. Christopher O'Day.

2. The Drugless Therapy of Diabetes.—Henry S. Stark states that he has experimented with many drugs in the treatment of diabetes and has recorded their effects, among them opium and its derivatives, arsenic salicylates, the coal tar preparations, potassium permanganate, antisyphilitic drugs where lues was an etiological factor, jambul, yeast, lactic acid bacillus, a number of proprietary preparations, and finally a whole galaxy of organotherapeutic drugs. As a result of these observations the conclusion is forced upon him that we cannot point to any drug which has a decided antiglycosuric effect, though we have a number of drugs which can provoke glycosuria. In order to test out the value of animal extracts and hormones he treated 20 diabetics with various pancreatic extracts, such as pankreon, 12 grains three times a day for four weeks, or pancreatin, 12 grains, three times daily. He has fed a number of diabetics with pancreas of the sheep daily for a number of weeks. As a result of all this he confesses that nothing more encouraging than a temporary or psychical improvement could be recorded. The only effect he did observe was a somewhat better digestion of fats, which was to be expected, in view of the fact that the pancreatic juice is largely concerned with fat metabolism. With thyroid and adrenalin he obtained no better results than with pancreatin, and the resort to pluriglandular therapy has not cleared the situation much. He expresses the opinion that the physician who views his diabetic patient as a psychological study will get further in relieving him than will he who religiously resorts to the drugs shelf. Diet, he agrees, is the mainstay of treatment, not the dietary methods formerly in vogue, but one that conforms with our modern conception of food metabolism. This allows a patient as much carbohydrates as he can assimilate, is satisfactory as to quantity and kind, and approaches the standard of a balanced ration. The writer discusses the dangers of a onesided diet, and considers the drugless therapy of diabetic coma.

3. The Limitation of Starvation in Diabetes Mellitus.—Thomas W. Edgar believes that too much stress is being placed upon the sugar content of the urine in diabetes, while other manifestations of the disease are neglected. He says we are treating diabetes (by starvation) in a manner that is neither actually nor relatively conducive to the health and economic status of our patients, to say nothing of the hardships inflicted. According to the rule in all seemingly chronic progressive diseases, and diabetes is no exception, the general practitioner bases his treatment on the hypothesis set by the investigator or research worker, who is too often a laboratory enthusiast without clinical experience. Pancreatic extracts are being placed on the market for the diabetic on the supposition that the pancreas is the exciting factor in the production of the disease, yet no definite lesion has been demonstrated to exist in the islands of Langerhans. The writer points out certain possible errors in the statistics that purport to show marked reductions in the number of deaths under the starvation treatment, and questions whether starvation is a harmless procedure. Personally he feels that it is dangerous and should never be indulged in without the supervision of a competent physician. Prognosis in a case of diabetes, whether severe or mild, should not be based on the rapidity of sugar reduction, but on the amount of food that can be ingested without the production of an excess of the lower fatty acids. Frequent starvation not only reduces the action of internal secretion to a minimum quantitatively during resistance, which in this case is carbohydrate, but drains the body of its glycogen content. This removes all available stimuli which might otherwise cause activity. The caloric power of the organism is reduced in its production of heat and energy. Resistance is lessened; metabolism is weakened; undernutrition invites infection, and tolerance decreases progressively. The writer records rather startling results from the use of a serum, which is prepared from the blood of rabbits after they have undergone a series of maneuvers capable of activating the various internal secretory glands to increased action. The serum contains the internal secretions in hormone form. With this serum he has been able to increase the carbohydrate tolerance of certain cases from 25 to 60 per cent., and in some cases cause an absolute arresting of the disease, as evidenced by loss of all subjective and objective symptoms, as well as gain in weight, which has been progressive.

1. Clearness in Medical Speech.—James S. McLester. (See MEDICAL RECORD, May 8, 1920, page 803.)

2. Treatment of Malignant Tumors of the Antrum.—G. B. New states that the usual treatment of malignant tumors of the antrum by resection of the upper jaw is followed by very frequent early recurrences, and a small percentage of cures. At the Mayo Clinic, during the past three years, 18 cases of malignant tumor of the antrum have been treated by the use of heat in the form of a soldering iron used as a cautery at a dull heat. The soldering iron is carried up into the antrum, and the entire growth is thoroughly cooked for from thirty to forty-five minutes. Radium salts or emanations in tubes are introduced into the antrum at the point at which it seems most needed, either at the time of the operation or from ten days to two weeks later, after some of the slough has cleared away. This method of treating malignant tumors of the antrum has been followed by no operative mortality and no postoperative chest complications. Of the 18 patients treated in this way three are dead, two have had extensive recurrences, and 10 are well and have had no recurrences over a period of from eight to twenty-eight months.

3. The Immediate Sterilization and Closure of Chronic Infected Wounds.—Dr. W. Wayne Babcock describes this method which he has used in more than 100 chronic wounds of soft tissues, and in about 250 cases of chronic osteomyelitis. It consists in four procedures carried out in one operation under anesthesia: Chemical sterilization of all sinuses and wound surfaces by the injection and application of a saturated solution of zinc chloride. 2. Delineation of infected areas by the injection or application of an alkaline ethereal solution of methylene blue. 3. Mass excision of the entire area of infection. 4. Wound closure with obliteration of all dead spaces. The zinc chloride is thoroughly injected under pressure or packed with small moist pledges of gauze into all sinuses and cavities, and rubbed very carefully over the scar and skin adjacent to the wound. When injected under pressure the general circulation must be protected by a tourniquet. The antiseptic staining solution, consisting of 20 mg., or c.c., of saturated alcoholic solution of methylene blue, 3 mg., or c.c., of caustic potash, and 5 mg., or c.c., of ether, made up to 100, is thoroughly applied to all eroded surfaces and injected under pressure into cavities and sinuses. As soon as this solution has evaporated, the exposed granulating surfaces are left dark blue, black, dry, bloodless on manipulation, and sterile. The coloring penetrates to a depth of 1 to 3 mm. Outside of this is a much wider zone of a vascular, grayish white tissue that has been sterilized and devitalized by the zinc chloride. The entire field is again painted with iodine, the instruments changed, and all infected tissues as indicated by the blue color excised.

7. The Catalase Content of the Cerebrospinal Fluid.—Abraham Levison and Frank C. Becht describe experiments in which the method of Becht was used and present tables which show that in nonmeningitis cases in which the number of cells in the spinal fluid is small, the catalytic power of the fluid is negligible; that in three cases of tuberculous meningitis and one case of anterior poliomyelitis, the amount of oxygen released was greater than in nonmeningitis cases in two instances, and in two quite comparable to the amount released in nonmeningitis cases; that in 10 observations on suppurative meningitis there was an increased amount of oxygen by no means comparable to the number of cells, but a fluid with a large number of cells was usually one with a high catalytic power. A perfectly normal fluid free from cells and coagulum was found to contain no catalase. The writers believe that the catalyse test as applied to cerebrospinal fluid is of no practical value.

3. Accessory Food Factors (Vitamines) in the Feeding of Infants.—Edward Mellanby discusses the relation between the fat-soluble A factor and the antiscorbutic factor in connection with infant feeding. He calls attention to the fact that according to MacCollum's rat-feeding experiments, the fat-soluble factor is absent from all vegetable fats. In rickets experiments, however, it seems definite that the amount of antirachitic factor is fairly high in some vegetable fats, such, for instance, as peanut, cottonseed, and cocoanut oils, and is only present to a small extent in palm kernel, linseed, and badassu oils. A second point the writer emphasizes is that fat soluble A does not appear to be necessary for growth in the case of puppies as it is in rats; the growth was often just as good when the diet was very deficient in this factor. It seems most likely that both (1) the difference in distribution of the fat soluble factor and the antirachitic accessory factor in vegetable fats, and (2) the importance of the fat-soluble factor for the growth of rats and its probable unimportance in the growth *per se* of puppies and children—could be explained by variations in the general and intermediate metabolism of these animals. The writer begs investigators in their further experiments not to mix up the growth experiments on rats and the rickets experiments on puppies. So far as his own experiments have shown, he finds that cottonseed oil is to be classed as one of the better vegetable oils in preventing rickets, and, taken in conjunction with the other conditions of diet as described by Hess and Unger, it does not appear to him surprising that rachitic symptoms did not develop in their cases. In his more recent experiments the writer has endeavored to link up the action of the vitamines with known dietetic substances. In doing this he calls attention to the well-known fact that active rickets is a rare disease in children over two years of age. On the other hand, arguing on the basis of results obtained in puppies, it is equally certain that, after this age, the diet of a child is often of a more rickets-producing nature—that is, it is composed more of bread and other cereals and less of milk. The only deduction possible from these facts is that after a time a child becomes more independent, *from the rickets point of view*, of its diet. After puppies have arrived at a certain age the writer has been unable to produce rickets on rickets-producing diets. His experiments have also shown that puppies developing rickets on these diets, if it was not too severe, and the general condition did not become too bad, recovery often took place, as indicated by radiographic examination, although the animal remained on the same diet and under the same conditions. The writer lays stress on the fact that, although rickets is primarily a deficiency disease of a dietetic nature, other metabolic conditions must necessarily be involved. In many experiments the only variable factor was bread, given to animals ad lib. Other things being equal, the greater the quantity of bread the greater would be the tendency to rickets. There was evidence on the other hand that protein had an antagonistic action to the development of rickets. There were also indications that casein had the same effect. Increasing

the protein factor alone, in the absence of the antirachitic accessory factor does not make a diet safe. The writer's view is that protein aids the antirachitic vitamine, so that less of the latter will suffice to keep the growth normal. Experiments as to the effect of exercise on the production of rickets seem to show that confinement on an adequate diet will not produce rickets, neither will freedom on a deficiency diet prevent rickets. Nevertheless, complete freedom will oppose to some extent the rickets producing effect of a deficient diet.

On the Relation of the Lipochroma Pigments to the Fat-Soluble Accessory Food Factor.—O. Rosenheim and J. C. Drummond have carried out experiments to determine whether the accessory food substance fat-soluble A is related to or identical with a member of the class of pigments which are found in association with fats. Their results seem to show that, while the identity of the fat soluble accessory food factor with a known lipochrome pigment appears to be improbable, there are reasons for assuming that it is in some manner associated with that class of substances.

1. A Clinical Lecture on the Treatment of Septic Peritonitis. F. J. Stewart.
2. A Lecture on the Soldier's Heart and War Neurosis: A Study in Symptomatology. Sir James Mackenzie.
3. Public Health Administration in Epidemics of Measles. John Brownlee.
4. The Physiological Cost of Muscular Work. A. D. Waller.
5. An Attenuated Tubercle Vaccine. Nathan Raw.

1. The Treatment of Septic Peritonitis.—F. J. Stewart says the indications in the treatment of septic peritonitis are to remove the cause; to provide drainage; to make good the loss of fluid, and to prevent or treat intestinal paralysis. He points out wherein the use of tubes and gauze drains have been ineffectual, and suggests a method of employing continuous irrigation. This method is as follows: After the bulk of pus has been mopped up with gauze sponges, several Carrel tubes are passed into the abdomen in different directions, one or more being carried down to the bottom of the pelvis. A large-bore rubber drainage tube is also carried down to the bottom of the pelvis and fixed to the lower part of the abdominal incision by a fishing gut suture. The upper part of the incision is partly closed, then lightly packed with gauze, which surrounds the tubes, and a large dressing applied. The patient is then placed in the Fowler position, with a bedpan beneath him, large wool pads intervening. Warm saline solution is permitted to drip continuously at about the rate of a drop a second. At this rate the amount of fluid run in twenty-four hours is about nine pints, which appears to be a sufficient quantity. The irrigation is continued from three to six days, according to the condition of the patient, when all the tubes are removed except one Carrel tube, which is allowed to remain for a few days longer. With this treatment no case up to the present time has shown any marked degree of intestinal paralysis.

5. An Attenuated Tubercle Vaccine.—Nathan Raw, after treating over 3000 cases of tuberculosis in hospitals with tuberculins from various sources, has come to the conclusion that the best results are obtained by treating human infections with bovine tuberculin and bovine infections with human tuberculin, since these two types of bacilli seem to be antagonistic to each other. He states that a pure culture of human pulmonary tuberculosis given him by Professor Koch, in 1905; one of bovine tuberculosis given him by Professor Calmette, and one of avian tuberculosis given him by Professor Bang of Copenhagen in 1905, have been subcultured every month since 1905 without any intermission, and to-day they grow true to type,, quite normally, though not so luxuriantly. Tuberculin prepared with these attenuated strains has given very satisfactory results and leads the writer to suggest that tuberculin should be prepared from attenuated and non-virulent cultures of bacilli; that it should be freshly prepared and used within a week; that it should be given in graduated and increasing doses at intervals of seven days; that acute reactions are unnecessary; that not less than twelve injections should be given at intervals of one week, though many more may often be required. The most favorable cases for treatment are local lesions, though early cases of pulmonary tuberculosis may be prevented from spreading to other parts of the lungs.

How to Remove the Craving for Alcohol.—Jaguaribe and Regnault begin by quoting the old proverb, "Who has drank will drink." We must distinguish between the wilful and the will-less drinker. Of these the former are less common. They are men of great energy and firmly believe they can protect themselves from all abuse of the drink. The habit is thus readily acquired and becomes associated with an imperious daily craving for the thrill of alcohol. When they seek to resist the craving they only defer it by some hours. They then deliberately weigh the apparent gains with the sacrifices and make a choice. The problem is a very old one, and the wise man has often played a trick on his subconscious self and its burning desire rather than to test his will too openly. Thus Cesar Borgia, after having become a heavy addict to wine, reduced the capacity of his glass by the cumulative addition of drops of melted wax until he had weaned himself from the desire. A more rapid process consists in rendering the drink nauseating by the addition of ipecac. It is the old trick of placing bitter substances on the nipple to wean a baby or on the finger tips to cure a child of nail biting. The search for substitutes has sometimes led to good results, but it usually is a case of robbing Peter to pay Paul. The psychology of the willful drinker is best explained by the creation of a second personality through the addiction, which is subject to its own laws. While the strong subject may become an aboulic as a result of prolonged addiction there are others who are aboulic by nature, and who put up no struggle at all. These are weaklings from the start, and demonstrate it in all aspects of life. The drug robs them of the little will power which they may have possessed. These subjects, which are rare in Latin peoples, are best adapted to psychotherapeutic management.

Le Nouveau Journal des Médecins.

March, 1920, i, 3.

Announcement to Readers.—Hyvert, the editor of the new series of an old periodical, makes an announcement to his readers of the scope of the same. The subject matter will be divided into twelve classes. First is original, or as the editor terms it, unpublished articles, either single and practical studies, or joint reviews. Next in order in importance are summaries of progress for the past month. Third are bibliographies without analysis of contents on various subjects. Book reviews come fourth. The fifth department is devoted to social medicine, and includes public health, while the sixth deals with therapeutics. Matter of interest to the profession, such as deontology, etc., comprises the seventh rubric. The eighth is extra-professional, to enable the medical reader to keep in touch with general science, arts, and literature. The ninth is devoted to recreation, physical culture, and sports. The tenth is devoted to medical news and information for the benefit of visiting doctors. The eleventh corresponds to a department of feuilleton or belles lettres, while the final section is given over to prizes for general competition. In the present issue we note a poem by a medical man, La Bonne, which was recently awarded a prize. Marcel Baudoin publishes a serial on the origin of the myths of the Centaur Chiron and Æsculapius.

Myelitic Form of Lethargic Encephalitis.—Weill reports a case in which myelitis was the dominant symptom. The encephalitic component was, however, well marked. This, taken in account with the new myoclonic cases, makes the term lethargic encephalitis too narrow and he would substitute the expression "Netter's disease" from the analogy of the "Heine-Medin disease" to express the totality of acute anterior poliomyelitis.—*Le Bulletin Médical.*

Book Reviews.

AN INTRODUCTION TO GENERAL PHYSIOLOGY. With Practical Exercises. By W. M. BAYLISS, M.A., D.Sc., F.R.S., Professor of General Physiology in University College, London. London, New York, Bombay, Calcutta, and Madras: Longmans, Green & Co., 1919.

THIS little volume deals with general or abstract physiology, which is a much broader subject than the applied physiology, which is of interest to, and is generally studied by, the professional medical, dental, veterinary, or agricultural student as part of his college curriculum. The general processes are of the utmost importance; but, unfortunately, they are frequently overlooked. The present book is an introduction to these general processes, and contains a discussion of many of the borderline studies dealing with chemistry, physics, and biology, which are so essential to a proper understanding of the subject of physiology. The author has divided his book into parts, the first dealing with the general subject, and serving as a text; and the second part dealing with the laboratory work. The volume is to be recommended to all students not only on account of its intrinsic merit and value, but also because there is such a dearth of books dealing with these general physiological processes.

PASTEUR — THE HISTORY OF A MIND. By EMILE DUCLAUX, late member of the Institute of France, Professor at the Sorbonne and Director of the Pasteur Institute. Translated and edited by ERWIN F. SMITH and FLORENCE HEDGES, Pathologists of the U. S. Department of Agriculture. Philadelphia and London: W. B. Saunders Company, 1920.

IT is not often, especially in medical annals, that a book nearly a quarter of a century old is deemed worthy of translation, and it is remarkable that a work of such absorbing interest as well as historical value should have failed all through these years to attract the notice of a translator. This is not a biography in the usual sense, but rather, as the subtitle expresses it, a history of a mind. It is an account of all Pasteur's scientific achievements—and even the well informed will be astonished when reminded of how numerous they were—prefaced in each case by a history of the previous work in the same direction by other investigators. The titles of the eight chapters of the book will suffice to recall the wide scope and the practical value of Pasteur's activity. These are: Works on Crystallography, Lactic and Alcoholic Fermentations, Spontaneous Generation, Wines and Vinegar, Studies on the Diseases of Silkworms, Studies on Beer, Studies on the Etiology of Microbic Diseases, The Study of Viruses and Vaccines —surely a long catalogue of contributions to science and of benefits to mankind. The tale is well told and the translators have succeeded beyond the ordinary in carrying over the charm of the author's style into the English version.

A TEXT-BOOK UPON THE PATHOGENIC BACTERIA AND PROTOZOA. For Students of Medicine and Physicians. By JOSEPH MCFARLAND, M.D., Sc.D., Professor of Pathology and Bacteriology in the University of Pennsylvania; Pathologist to the Philadelphia General Hospital. Ninth Edition. Philadelphia and London: W. B. Saunders Company, 1919.

THAT a text-book of bacteriology should reach its ninth edition in the course of twenty-three years service to the profession, is in itself evidence of the intrinsic worth of the work. McFarland's book has long had an enthusiastic following that is apt to be much increased by the appearance of this edition. The author states in his preface that the present revision was accomplished under difficulties, the greater part of it having been done during the time when he was on active service in the army. It is probably because of those difficulties that the reviewer is able to detect certain omissions which it could be wished had not been made. There is practically no discussion of the hydrogen ion concentration of culture media, a subject that is acquiring great importance. The statement that the spores of *B. botulinus* are killed by exposure to 80° C. for one hour seems to be contradicted by recent work in food poisonings. The discussion of the various types of streptococci is inadequate. It would seem that rather more space might have been given to *B. paratyphosus*. Wound bacteriology receives but little attention, as perhaps is proper since we trust the need for it has passed. The author appears to believe that trench fever and spirochetosis icterohemorrhagica may be one and the same thing. But it is easy to carry such criticism to an unfair extreme, and these comments will not injure the high standing in which this work has always been held. It is unusually complete and the information it contains is very accessible.

COMMON DISEASES OF THE SKIN. With Notes on Diagnosis and Treatment. By G. GORDON CAMPBELL, B.Sc., M.D., C.M. Lecturer on Dermatology and Pediatrics, McGill University; Physician to the Montreal General Hospital. New York: The Macmillan Company, 1920.

IN this little book there will be found a short description of most of the commoner diseases of the skin, with indications for their treatment. The book abounds in illustrations, the text being less than one-half of the volume. As a rule a page or two suffices for the description of the disease under discussion, and it is only such important topics as Eczema and Syphilis which tempt the author to be more liberal. Needless to say, in a book of this size there is no discussion of various theories and points of etiology and pathology; the student is taught to recognize the disease, and is then instructed as to its treatment. This work should be very popular with students and practitioners; it is, certainly, of more real value than many of its larger and more pretentious competitors.

A LABORATORY MANUAL OF PHYSIOLOGICAL CHEMISTRY. By ELBERT W. ROCKWOOD, M.D., Ph.D., Professor of Chemistry and Toxicology in the University of Iowa. Fourth Edition. Philadelphia: F. A. Davis Company, 1919.

THIS small volume provides an outline for a course in physiological chemistry rather more full than would be needed in any one course but containing enough material so that an instructor may choose somewhat the matters which he presents. The present edition has been rather thoroughly revised and somewhat enlarged above the previous edition, which appeared nine years ago. The text is condensed so as to offer a sufficient skeleton upon which the student should build his notebook and appears to be satisfactorily complete. It should prove a useful aid in giving a course in this subject.

THE MEDICAL CLINICS OF NORTH AMERICA. November, 1919. Mayo Clinic Number. Volume 3, Number 3. Published bi-monthly by W. B. Saunders Company: Philadelphia and London.

IN this number the conventional clinic form of the presentation of the subjects has been abandoned for the majority of the articles and the presentation is made as would be the case for regular journal articles. Whether on this account or because of the rich material presented the number seems to create a more favorable impression than any of its predecessors. There are twenty-three contributors who have filled a volume of very nearly three hundred pages with discussions ranging from retinitis circinata to leprosy. Perhaps the most striking is a series of some seven articles in conditions of the spleen and the blood, in which is given a number of sharply drawn pictures and a large amount of valuable information. One of the especially attractive features is the bibliography which accompanies the articles. It is our impression that this is the best number of the clinics which has appeared.

THE MEDICAL CLINICS OF NORTH AMERICA. January, 1920. Boston Number. Volume 3, Number 4. Published bi-monthly by W. B. Saunders Company. Philadelphia and London.

IN this number there are contributions from seventeen clinics held in four Boston hospitals and one article from the Harvard Medical School. The majority present cases of interest and importance to the physician. Rosenau gives the results of experiments with feeding canned foods. The volume is interesting in the wide scope of the presentations and the attractive manner in which the cases are discussed.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Seventy-first Annual Session, Held in New Orleans, April 26-30, 1920.

SECTION ON OBSTETRICS, GYNECOLOGY, AND ABDOMINAL SURGERY.

First Day—Wednesday, April 28.

DR REUBEN PETERSON, OF ANN ARBOR, MICH., IN THE CHAIR.

Chairman's Address: The Future of Obstetrics and Gynecology as a Specialty.—Dr. REUBEN PETERSON said that the title of the paper suggested the view which he had long held with regard to the specialty concerned, namely, that obstetrics and gynecology should be linked together in a single specialty, and should not be considered as two distinct specialties. It should be known as obstetrics and gynecology and not the reverse, since it seemed illogical to place that which had to do with disease in advance of that which occurred before disease appeared. Gynecologists as a class had confined themselves to the surgical aspects, openly declaring that they cared nothing about obstetrics and did not care to learn. It was inevitable that they should become discontented with the small field of surgery and that they should push on to a broader field. Thus one saw the gynecologist operating upon men as well as women, calling himself an abdominal surgeon. The general surgeon disapproved, and the tendency to include gynecological surgery with abdominal surgery had increased. Had the gynecologist stuck to his specialty this would have allowed him to devote more time to the practice of obstetrics, thus paving the way to a true specialty, the prevention of disease. The gynecologist had only himself to blame. He had thrown himself into gynecological surgery until nothing else interested him. One reason for this state of affairs was that medical colleges had divorced obstetrics from gynecology and had given undue prominence to surgery. The surgical end of the specialty had been given attention to the neglect of the groundwork which was absolutely essential in any field. If there were to be a future for obstetrics and gynecology it must come through hospitals and schools organized on the right basis. If the two divisions were to be united and flourishing immense benefit to mankind would result, but if the two remained separate in the teaching institutions, in two generations there would be no obstetricians or there would be no distinction between the two specialties. The surgically inclined bright young man would not choose gynecology as a specialty when he could enroll in general surgery and have the whole body for his field; he would not become a "man midwife." Obstetric material must always be an immense expense to institutions; it was composed of so-called charity cases, patients who sought institutions because they knew they would be properly cared for. The out-patient obstetric department flourished. It was cheaper to build up an out-patient obstetric department than to meet the expense of the in-patient obstetric department. If adequate patients were furnished for the two under one head the subject would be well taught; if, on the other hand, the policy selected separated them, the opposite would be the case, and obstetrics would not flourish. Gynecology would become more and more a surgical specialty, there would be no valid excuse for not making it a branch of general surgery, the chairs of gynecology would disappear, and the chairs of clinical gynecology would be absorbed by general surgery. United with obstetrics, gynecology would survive; separated from it, it would cease to exist. The two divisions should be treated as one subject; it would be comparatively easy, under such circumstances, to see that the field of surgery was not over-emphasized. Technical skill in obstetric and gynecological surgery should be obtained by cooperation with the general surgical staff. In fact, this free interchange of services should not be confined to surgery, but should apply to all departments of a hospital.

Chronic Leucorrhea: Its Pathology and Treatment (Lantern Demonstration).—Dr. ARTHUR H. CURTIS of Chicago reported the findings of years of study devoted to the clearing up of the problems associated with chronic leucorrhea. In a considerable proportion of cases this condition had been found associated with chronic cervicitis, and chronic endometritis had been frequent. Endocervical granulations and strictures had also been encountered in association with chronic leucorrhea. Granulations were found anywhere in the canal, strictures at the surgical os or at higher levels. Infections of the urethra, and of Bartholin's glands and Skene's ducts were also found. Acute leucorrhea tended to be self-limited if left alone; it could be treated almost any way and would finally disappear. In chronic leucorrhea the surgical treatment of gross lesions and the use of radium were indicated. If necessary, the infected ducts should be incised and fulgurated. Radium given in proper dosage and with sufficient intervals would not result in the production of artificial menopause. In some cases it was necessary to choose between improvement of the leucorrhea and the production of the menopause. Treatment for the cure of leucorrhea would not necessarily cure sterility; sometimes, however, pregnancy followed such treatment in cases in which there had been complaint of sterility.

Dr. FRANCIS LE S. REDER of St. Louis, Mo., in opening the discussion, expressed appreciation of the work which Dr. Curtis had devoted to this subject, which was one of great importance. The genital tract of woman in a normal condition was in a state of leucorrhea. There had been a tendency to disregard the meaning of the word leucorrhea, the term being applied to almost any discharge from the genital area. When might one consider leucorrhea chronic? When the woman consulted the physician. It was to be regretted that women disregarded vaginal discharges for so long, because microorganisms rendered such discharges very difficult to correct. The mucosa of the genital tract was not separated from the deeper structures by an areolar layer as in the digestive tract, and ulcerated or occluded glands deep in the muscularis furnished splendid recesses and abiding places for microorganisms. The Neisserian gonococcus kept up the discharge in the majority of cases. If one could get a history leading one to suspect this infection, very well; but it was exceedingly difficult to distinguish this diplococcus from other forms of diplococcus present. When one considered the subdivisions of leucorrhea it became absolutely necessary to differentiate vulvar from vaginal. Should it trespass upon the cervical region it would be exceedingly difficult to dislodge it. It usually required a plastic operation to uproot it.

Dr. WATKINS of Chicago considered the paper in line with valuable advances which had been made and which were being made in the pathology and treatment of the endometrium. It followed up the very important work which had demonstrated that the amount of endometrium obtained at curettage depended upon the menstrual cycle and had very little relation to infection. Bacteriologically, the work done by Dr. Curtis and others had shown that in the majority of cases the cavity of the uterus was sterile. Bacteriological invasion was limited to the cervix. This meant that curettage had been resorted to too often. There was almost no indication for curettage of the endometrium except for diagnostic purposes. The only reason that curettage had helped a number of cases of uterine leucorrhea was because it had dilated the cervix. The question of the cure of the infection was a very important one and one very frequently neglected. He emphasized the point that erosions of the cervix would almost invariably heal after the use of radium. It was very important to regulate the dose so as not to influence permanently the function of the ovary. The action of radium diminished the cellular tissue and increased the amount of connective tissue cells, and in this way it often acted as very efficient drainage of the deep glands of the cervix.

Dr. RANSOHOFF of Cincinnati asked Dr. Curtis whether he employed curettage preliminary to the use of radium, and if so, whether the curettage had any influence on the ultimate outcome. He had used radium for five or six years and he considered it contraindi-

cated in the presence of infection in the tubes. Whether the disease itself were of sufficient gravity to warrant rendering a woman sterile and to deprive her of the menstrual function at an early age was a question. He also asked the essayist what filtration he employed in using radium.

Dr. T. SALATICH of New Orleans called attention to the importance of malposition of the uterus in these cases. In the presence of backward displacement of the uterus treatment of the leucorrhea would not cause it to cease. He cited a case in which the patient's face was full of acne, and in which headaches and some joint trouble were complained of at times. The cervix was entirely devoid of mucous membrane. He curetted and applied iodine or other forms of medication after curettage, with good results.

Dr. CURTIS, in closing the discussion, said it was not necessary or indicated that one perform preliminary curettage. He had resorted to curettage only for diagnostic purposes, except in a few instances. Even in these cases it was not an advisable therapeutic measure. He did not believe radium advisable where the infection was in the deeper structures. He did not believe in giving enough radium to sterilize the patient, or to interfere with ovarian function. In three cases he had given enough to render the patient sterile. Regarding infiltration, he used a half millimeter gauze screen surrounded by dental rubber. Innumerable remedies had been tried for leucorrhea, but after a time none had prove efficacious.

Conservation of the Menstrual Function.—Dr. WILLIAM J. MAYO of Rochester, Minn., said the surgeon usually approached his work with the physical condition of his patient in view. He achieved tangible success, but sometimes without the gratitude of his patient. Physical success was sometimes obtained at the expense of nervous or psychic disturbances, whereas the same physical results might be obtained in some other way. The instability of the central nervous system was frequently the cause of unnecessary operations, the uterus, the ovaries, and the tubes being the chief sufferers. In malignant disease of the female genital organs radical operation was necessary; in cases of benign neoplasms and inflammatory disease, however, the future condition of the patient, psychic as well as physical, must be remembered. With the growth of knowledge the practice of removing the ovaries had largely given place to conservative operations, with the result that instead of the removal of the ovaries there had been developed a lot of tampering, often resulting in removal later. Patients sometimes returned with what they thought were adhesions. Adhesions located by the patient and not by the surgeon were of little significance. The lesson to be drawn from the study of the ovarian secretion in relation to the general endocrine system, and from the various experiments with ovarian transplantation, was that removal of the ovary was seldom indicated for inflammatory conditions, and that enough ovarian tissue should be left to maintain menstrual function. Removal of the ovary was seldom necessary for dermoid cyst. Independent of its rôle in reproduction the ovarian secretion had a marked effect upon the nervous system. Nervous and psychic influences were exaggerated by operations which stop the menstrual flow. Conservation of the ovary for the effects of its endocrine function was second only to the preservation of its reproductive function. The sacrifice of the reproductive and menstrual functions was not confined to the ovary, but applied to operations on the uterus, especially for myoma. Many a uterus had been sacrificed when myomectomy would have sufficed. After the age of forty-five, hysterectomy was probably the best procedure. It had been argued that myomectomy was more dangerous, but in a series of more than seven hundred cases this had not been found to be the case. In 743 cases secondary hysterectomy had been necessary in only ten. In this series 33 women had had one child, 11 had had two or more children, and 15 had normal pregnancies at the time of the investigation. Twenty-three women who were sterile at the time of the operation had borne children afterward. Radium in selected cases had no competitive standing with myomectomy. It might be more destructive than operation. One must sharply distinguish between conservation and non-operation. It had frequently been observed that women had borne children despite myomatous growths, and many such cases were being treated with radium. This was not wise. Menstruation might disappear never to return after even an ordinary amount of radium. Total hysterectomy was more satisfactory than subtotal. In closing, the essayist reiterated that conservation of the menstrual function was of the utmost importance even if pregnancy was not possible. The surgeon who removed all these tissues was assuming a great responsibility, for the nervous disturbance which resulted might be such that the patient could never readjust herself.

Dr. C. JEFF MILLER of New Orleans said it had not been his experience that myomectomy was more dangerous than hysterectomy. It had been considered more dangerous because of the possibility of hemorrhage, but advances in technique had overcome this. He was doing twenty-five to thirty per cent. more myomectomies than formerly. If one saved merely the mucous membrane one might preserve the menstrual function, but there was a likelihood of menorrhagia and sometimes metrorrhagia. He agreed with the essayist that total hysterectomy was more satisfactory than subtotal, and for the last three years in all cases in which the uterus had had to be sacrificed he had resorted to complete hysterectomy. There was no more hemorrhage, and the after-results were better than with sub-total hysterectomy. He employed the supravaginal method. He had contended all along that myomectomy was a more conservative operation than the application of radium. In a certain percentage the growth would return, but in the average case permanent shrinkage was obtained. For a single tumor in a young woman myomectomy was the operation of choice. After forty-five radium or more radical surgery might be employed. Resection of the ovary belonged to the surgical junk-heap. It was better to do a transplantation operation than to leave a small amount of ovary with the blood supply destroyed. He had had good results in twelve or fifteen cases. The patients continued to menstruate for from two to four years, then gradually ceased to menstruate without the disturbances associated with the abrupt cessation.

Dr. JOHN OSBORN POLAK of Brooklyn, N. Y., said much of the damage in cystic conditions of the ovary was due to circulatory disturbance; when that was corrected the ovary regenerated itself and the so-called cyst dropped back into the pelvis.

Dr. ROBERT T. MORRIS of New York City said he had changed his mind so many times on so many subjects during the last thirty years that he had no confidence in anybody who had confidence in him. During these thirty years he had spoken on the main theme of Dr. Mayo's paper as one crying in the wilderness. There were three eras of practice, the heroic, the anatomic, and the pathologic, to which might be added a fourth, in which the patient was given home rule, turned over to himself or herself. In the third era, the pathologic era, the surgeon had conscientiously done an enormous amount of damage. He meant well but did not know. At the present time, with the new group diagnosis, the patient, like the prisoner at the bar, must await the decision of at least "twelve good men and true." The surgeon who boldly came to a conclusion as to when to operate and under what circumstances, would want to have personal knowledge of these "twelve good men and true." Conservation of the ovary had been overlooked, but when it began to receive attention there was a tendency to place the blame for symptoms upon the wrong organ. Conservation of the ovary might be obtained by means of ovarian grafting, a healthy part of the patient's own ovary being placed somewhere within her economy. The time would perhaps come when heteroplastic transplantation might be successfully performed. The graft was now destroyed by antibodies, but it might be possible to make antibodies which would be destructive to these other antibodies. Many men had argued in favor of the removal of the uterus in cases in which Neisserian infection was present, with its terminals. In view of the fact that spontaneous recovery sometimes occurred in these cases the surgeon should talk freely and frankly with the patient, telling her the possibilities of pregnancy if the ovary or a part thereof be left, and

other features of the case. The time had passed when the surgeon was a thing apart from his clientèle.

Dr. ALBERT J. OCHSNER of Chicago called attention to the frequency of reinfection in cases operated upon without removal of the uterus in patients from the lower walks of life, such as one encountered in clinics and city hospitals. In these patients the function should be abolished by the removal of the organs. He had recently looked up the literature concerning the relative mortality of myomectomy and hysterectomy, and had found that a large proportion of deaths after complete hysterectomy were due to pulmonary thrombus. The pulmonary thrombus was almost invariably due to lack of hemostasis. The correction of this by the proper use of sutures had greatly reduced the mortality.

Dr. MAYO, in closing, said the discussion had brought out the fact that the gynecologist, when he worked above the pubic bone, was a first-class general surgeon. A number of years ago Dr. Ochsner had called his attention to the matter of tying the sutures too tight in myomectomy cases, and since he had taken care not to tie them tight enough to cause bleaching of the tissues he had had no trouble.

Relation of Hyperplasia of the Endometrium to So-called Functional Uterine Hemorrhage (Lantern Demonstration).—Dr. EMIL NOVAK of Baltimore, Md., discussed the frequency of so-called functional uterine hemorrhage, a term which embraced such varieties as the hemorrhage of puberty, idiopathic hemorrhage, metropathic hemorrhage, and functional climacteric hemorrhage. In most cases of uterine bleeding the cause could be found in some pelvic organs. In some cases the cause was clear, the hemorrhage being due to the actual opening up of the blood vessels by erosion; in other cases the cause of the bleeding was not so obvious. The latter type was represented by inflammatory conditions. The class of cases considered in the paper represented those in which the bleeding occurred in the entire absence of pelvic disturbance. The various explanations as to their cause had been far from convincing. These types of bleeding occurred at the two extremes of menstrual life, being more frequent at the later stage. While there was usually no gross lesion, the endometrium often showed typical hyperplasia. This hyperplasia was characterized by overgrowth of the endometrium, sometimes showing several layers of epithelium, sometimes large and cystic glands, not endometrial cysts, however. The stroma was over-abundant, and sometimes mitotic figures were seen. These features were illustrated upon the screen by the findings in various cases. The fact that this hyperplasia and this functional bleeding occurred at the two extremes of menstrual life had given rise to the question of the possible influence of the endocrine system. Curettage in itself rarely cured these cases. When bleeding recurred after curettage, repetition of the curettage revealed endometrium just like that obtained from the first curettage. In other words, one merely scraped away an outward manifestation of an underlying cause. Radium and *x*-ray exerted a very beneficial effect upon this type of bleeding. It occurred during the period of ovarian function, and could be stopped by removal of the ovary. For these and other reasons it was believed that hyperplasia was not a primary condition, but that it was due to a disorder of the internal secretory function of the ovary. The lesson to be drawn from the study was that the gynecologist should not only look for the causes of uterine bleeding in anatomical conditions but should also search for disturbances of physiological function. Why say that hyperplasia caused abnormal uterine hemorrhage? Why not say that the hyperplasia was due to some underlying cause?

Dr. LUCIUS E. BURCH of Nashville, Tenn., said hyperplasia might be associated with cancer, abortion, fibroid tumor, extra-uterine pregnancy, and so-called endometritis associated with pelvic inflammation. Functional bleeding occurred only during the period of sexual activity and was not associated with any palpable or visible pathological condition of the uterus or appendages. Hyperplasia was a secondary condition, and the essayist's arguments concerning the etiological influence of endocrine disturbances seemed unanswerable. In his experience the curet did no good in this the treatment of the type of uterine bleeding under consideration, or in any other condition, and should be used only for diagnostic purposes.

Dr. NOVAK, in closing the discussion, emphasized the point that the bleeding in these cases was characteristically of the type of metrorrhagia which indicated that the corpus luteum exercised some influence. He agreed as to the limitation of curettage. If the endocrine theory of the causation of the disturbance be accepted, the question of treatment would necessarily involve organotherapy. This would differ in different cases. Corpus luteum by mouth had been used on the basis that ovarian change existed as a consequence of change in the corpus luteum. Repeated curettage might exercise a favorable influence perhaps by stimulating ovarian function. Treatment might be summarized, in sequence, as curettage, organotherapy, radium, *x*-ray, and possibly hysterectomy.

A Plea for Total Hysterectomy in the Operative Treatment for Fibroid Tumors of the Uterus in Parous Women.—Dr. JOHN OSBORN POLAK of Brooklyn, N. Y., pointed out that all fibroids of the uterus did not require radical operation. Fibroids in non-infected, non-parous women did not mean total hysterectomy. His consideration of the subject was confined to parous women. The cervix of the parous woman was frequently the seat of lacerations and hyperplasia, and subtotal hysterectomy therefore failed to cure the leucorrhea, metrorrhagia, and backache. Better follow-up work had shown that cancer of the retained cervical stump after supracervical hysterectomy was more frequent than was generously supposed, the cervix with its ulceration and erosion paving the way for epithelioma. The fact that this was not fanciful was proved by the frequent finding of cancer in such cases. By personal communication and a review of the American literature he had collected 253 cases of cancer of the retained stump. All except five of the patients were married and had been pregnant or had had trauma of the cervix, such as dilatation and curettage, one or more times. These cases included all in which cancer made its appearance within a year after subtotal hysterectomy. It had been shown by routine sections in over nine hundred specimens that cancer existed in over two per cent. of all cases of subtotal hysterectomy, in cases in which there was nothing suspicious in the cervix at the time of examination, the cancer appearing in from five to twenty years. The parous cervix was always problematical and cancer could not be excluded by the absence of the finding of cancer cells in the scrapings. From his study of the subject he had concluded that when it was necessary to operate for fibroid tumors of the uterus in parous women, or those who had had trauma or infection of the cervix, total hysterectomy was the operation of choice. The technique which he employed was described by means of lantern slides.

Dr. EDWARD E. MONTGOMERY of Philadelphia said the history of malignancy had shown that in the majority of cases the cervix was the seat of the disease, in women who had given birth to children, this portion being subjected to the greatest injury. There was interference with the circulation of the cervix after removal of the body of the organ. It was not difficult to understand why malignant degeneration should involve such a cervix. It was not always so easy to perform the operation of total hysterectomy as one might suppose from the slides presented by Dr. Polak. Numerous technical difficulties might arise. It was sometimes necessary to remove a number of fibroid growths before one could proceed with the operation.

Dr. SCOTT of Memphis, Tenn., thought it would be interesting to know how many thousands of subtotal hysterectomies were performed in the series from which the 253 cases mentioned by the essayist were taken,—probably twenty-five thousand. In the nine hundred cases mentioned doubtless quite a large per cent. would have died. In the two per cent. of cancer the patient still had a chance for life. He believed that there were cases of cancer which existed at the time of the subtotal hysterectomy, and if the operator were careful enough he would be apt to find an extensively diseased cervix. He did not advocate supra-vaginal hysterectomy in every case in which the cervix was diseased, but if the patient were properly examined in every case where this operation was contemplated

there would be no occasion for overlooking the disease so often.

Dr. POLAK, in closing the discussion, referring to Dr. Montgomery's remarks concerning the difficulties of the operation, said the unskilled man would have difficulty, but if he would follow out the technique as shown it was amazing how he would be able to do his more difficult cases. The same applied to the Wertheim operation. By isolating the ureters in simple fibroid cases he would soon find that he could isolate them in the more difficult cases. It was seldom that one could make serial sections of the entire uterus in these cases. In the nine hundred cases to which he had referred serial sections had been made.

Hernia of the Ovary.—Dr. WILLIAM W. GRANT of Denver, Colo., thought hernia of the ovary had received less consideration than it deserved. Although long known, little had been written about this condition because of its infrequency. Of the few cases reported, the majority had been of the inguinal variety, the femoral type being very rare. He reported two cases of crural hernia with operation. The diagnosis was generally determined at the time of the operation. There was no absolutely conclusive evidence of the contents of the sac except by demonstration. The technique employed in the correction of this condition was described in connection with one of the cases reported. The character of the operation was governed by the conditions existing in each case.

Dr. GEORGE H. LEE of Galveston, Texas, reviewed briefly the cases of hernia reported. From the statistics recorded it would seem that inguinal hernia occurred sixteen times as frequently as femoral hernia. Femoral hernia was more frequent in women than in men. Relaxation, intraabdominal pressure and child bearing were concerned in the causation of the condition.

Dr. GOLDSPOHN recalled a case of hernia of the ovary in a woman eighty years of age, which was relieved by operation. During the operation the ovary was found in a strangulated mass. The patient recovered and so far as he knew there was no recurrence.

Dr. GRANT, in closing the discussion, said it was the usual experience that the diagnosis of the contents of the sac in these cases could be made only by examination. In the specimen which he presented he thought the cyst present was ovarian rather than parovarian because of the character of the contents. Ordinarily a parovarian cyst was filled with a white, clear liquid, whereas an ovarian cyst contained a straw-colored liquid. Whether the original hernia was the ovary or a cyst he did not know.

Results of the Exposure of Animal Ovaries to the Rays of Radium (Lantern Demonstration).—Dr. JOHN M. MAURY of Memphis, Tenn., demonstrated the changes which take place in the ovaries as the result of exposure to the rays of radium, showing the difference between the treated and the untreated ovary. The theory was that radium exerted an effect upon the young follicles. No account seemed to have been taken of the effect of the radium upon the endometrium. He had not been able to substantiate the theory by microscopical examination. It was necessary to examine a large number of normal ovaries in order to determine the changes which took place under the radium rays. The difference between the ovaries of the rabbit and the human had to be taken into account. After the application of radium the animals were killed, this being done at varying intervals, the ovaries removed, and paraffin sections made as soon as possible. Serial sections were made, about 150 or 200 sections of each ovary. The ovaries varied in size, this variation being attributed to the number of corpora lutea present. The connective tissue cortex varied. The greatest variation was in the condition of the follicles; in some there were no follicles alive or dead, in others they were present in varying stages of degeneration. The blood vessels showed no sign of endarteritis. Some of the animals became pregnant and did not miscarry. From this study it was concluded that six hundred milligram-hour doses of radium did not produce degenerative changes in the follicles of the ovary.

Dr. HENRY SCHMITZ of Chicago, in studying the literature of the subject under discussion, had been surprised at the difference of opinion regarding the effect of radium rays upon the ovary. Dr. Maury's observations were timely and valuable. From his own observations he was convinced that, for physical reasons, radium, as ordinarily employed, could exert no effect upon the function of the ovary. Dr. Maury had shown its impossibility from a biological point of view.

Second Day—Thursday, April 29.

Abnormal Lactation (Lantern Demonstration).—Dr. MATHIAS J. SEIFERT of Chicago based this consideration of the subject on a surgical case of eccyesis. He gave a comprehensive review of the literature, including the consideration of lactation from its different social aspects—in the society woman, in the woman of the poorer classes, and in the woman of the tribes and races of uncivilized peoples; the importance of normal lactation to the well-being of a mother and her offspring; a discussion of the common belief that lactation prevented conception, with statistics; overlapping pregnancy and lactation; hyperlactation in its relation to pelvic inflammations, and in relation to diseases of the eye and brain; reports of cases of lactation in the infant, in the virgin, in the superannuated female, and in the male; reports of abnormal lactation in animals. A thorough understanding of the function of these glands was indispensable.

Dr. WILLIAM KOHLMANN of New Orleans, La., called attention to the possible legal significance of abnormal lactation. From a practical point of view it was most important, especially defective secretion. Hypersecretion began with an amount above two pints a day. Many women were inclined to secrete a great deal of milk when they were not well and strong. Under such circumstances the milk was not of good quality, and had a bad effect on the digestive organs of the child. There seemed to be a decreasing number of mothers able, because of lack of secretion, to nurse their children, and there was little that could be done to stimulate secretion. Keeping up the nutrition and regulating the general health were important in this connection.

Intrauterine Insufflation of Oxygen (Artificial Pneumoperitoneum) for the Determination of Patency of the Fallopian Tubes in Cases of Sterility.—Dr. ISADOR C. RUBIN of New York City recognizing the impossibility of determining the patency of the Fallopian tubes by physical examination, had made injections of substances opaque to the roentgen ray, such as collargol and thorium, into the uterine cavity for the purpose of determining whether or not the Fallopian tubes were open in any given case of sterility. This had been tried in a limited number of cases. He had recently supplemented this by the intrauterine inflation with oxygen, and had found this procedure of far greater value. In cases with patent tubes the oxygen passed into the peritoneal cavity and produced an artificial pneumoperitoneum, which was easily demonstrated by fluoroscopic examination. He had employed the method in about thirty-five cases, in none of which had there been any untoward symptoms or sequelæ. The patients had left for home immediately after the examination, and had returned for subsequent observation. The technique and apparatus employed by the essayist were described by means of lantern slides. He showed the picture of a woman of more than forty who had been sterile for over twenty years, the sterility being attributed to fibroids. He attempted inflation and found that the oxygen did not go through the tubes. He at once concluded that the tubes were the cause of the sterility and that the fibroids were incidental. At operation a double hydrosalpinx was found. The same volume of oxygen which could be introduced clinically could be introduced into this extirpated specimen. The essayist presented on the screen a table showing the results in thirty-three cases, which were studied from the points of view of the diagnostic value of the method, the safety of the method, including the question of infection; the question of embolism; the practical problem of how much to introduce and under what pressure. In the cases in which no pressure was used there were no peritoneal symptoms. In selected cases the method obviated the necessity of surgical exploration, and was particularly serviceable in obscure cases.

Dr. JOHN OSBORN POLAK of Brooklyn, N. Y., con-

sidered this a most ingenious method for establishing the patency of the tubes. In the series reported by the essayist there had been no calamities, and yet the speaker was not convinced that it was a safe procedure to introduce oxygen into the peritoneal cavity by way of the Fallopian tubes. The irritability of the uterus was to be considered. In some women the manipulation of the cervix or the introduction of anything into the cervix would cause violent intrauterine contraction. The selection of the cases was a difficult problem which, in his opinion, militated against the general use of the method, despite its many apparent advantages. The investigation of the factors which produced sterility in a given case was of importance. In a series of six hundred cases investigated it was found that four hundred had tubal disease. This was definitely proved in over fifty per cent. of the cases by abdominal section, to which the patients consented. In ninety cases investigation showed the man to be absolutely impotent. The history of the case was a significant factor in determining the cause of sterility. In many of the conditions which contributed to sterility it was much safer to resort to abdominal section than to inflate the tubes and peritoneum with gas.

Dr. RUBIN, in closing the discussion, said the objections raised by Dr. Polak were not unknown to him. These very objections had had to be overruled, and the only way they could be overruled was by actual experimentation. So far as the irritability of the uterus was concerned, he had found that the vast majority of patients tolerated the oxygen very well. The introduction of oxygen was more of a procedure, so far as the tolerance of a diagnostic method was concerned, than was the introduction of a cystoscope, and the bladder was no more sensitive to the cystoscope than was the uterus to a sound. There were cases, of course, in which the method under consideration could not be used, but even in these cases it was absolutely safe. Of the safety of the method he was absolutely sure. It was surprising to see how much pressure the uterus would stand. When the tubes were not potent, absolutely closed, no oxygen would go through. He was convinced that the method had a distinct field of application.

The Treatment of Obstinate Occipitoposterior Positions.—Dr. JOSEPH B. DELEE of Chicago sent this paper which, in the absence of Dr. DeLee, was read by Dr. Francis Le S. Reder of St. Louis. In spite of all that had been said concerning this mechanism, it was frequently overlooked. It was responsible for thousands of infant deaths and many material deaths each year, and caused great maternal and infant suffering. In the majority of cases, if given time enough, rotation would take place spontaneously, the case terminating as an occiptoanterior. The majority would so terminate without injury to the mother or the child. In some cases, however, the labor would be so prolonged that both mother and child, particularly the child, would suffer injury. The word obstinate was applied to occiptoposterior positions that remained such. The most important matter in cases of abnormal rotation was their recognition. The various contributing factors were considered. There were two classes of cases, those in which the head was engaged, and those in which it was above the inlet. When the head was high and floating, interference was not necessary. Careful search should be made for conditions which should be treated. Watching and waiting were necessary. The patient should lie on the side to which the occiput pointed. Morphine and scopolamine were indicated in the early stage, but one should not let the labor drag on too long. After complete dilatation of the cervix one should wait an hour or two for the head to engage; if it did not engage, two procedures were indicated—first, version, followed by extraction; second, manual correction of the position, under deep anesthesia. Manipulation might fail for various reasons, when cesarean section was indicated. A warning was sounded against the use of forceps in high head cases. The child was always injured, sometimes killed, and the mother always injured. The details of the procedures employed by the essayist were given.

Dr. NEWMAN of San Diego, Calif., considered the condition under discussion one of the bugbears of obstetrics; it always had been, and he feared it would continue so in spite of the admirable paper and valuable suggestions of Dr. DeLee. Many factors had to be considered—the delay; the possibility of injury to the child; the mischief done to the soft parts of the mother; dealing with the case not too hurriedly, not without careful diagnosis, not without knowing fully the conditions present. The essayist had vision, and while he had added something to the sum total of dealing with these cases, yet the speaker thought there were other hopeful methods, among which might be mentioned the observation of the case without interference, without disturbing nature's method of handling these cases. A large percentage of these cases, if not handled too hurriedly, would progress satisfactorily, and birth would take place without accident. On the other hand, where conditions pointed to mischief and injury, trouble should be forestalled by doing work which would be effective and he thought cesarean section might be called into play here for the well being of both child and mother. One should not be too hasty in resorting to operative procedures, but one should also consider the after-health, the morbidity, that resulted from these procedures, and the injuries from which neither mother nor child ever recovered.

Dr. JOHN OSBORN POLAK of Brooklyn, N. Y., said the cases under consideration could be classed broadly as those in which the head engaged, and those in which it did not. Whenever the head did not engage there was apt to be present some obscure condition which prevented its doing so. In other words, there was a faulty inclination of the pelvis, the most frequent manifestation of this being found in funnel pelvis. The higher degrees of funnel pelvis all had faulty inclination, and these were the cases that did not engage. Where the head engaged, in the majority of cases delivery could be made per vaginam. In his clinic he and his associates had long since given up vaginal examination, using rectal and abdominal examination instead. They used no bags or other methods of dilatation. Rest by morphine and scopolamine was advocated. When the head did not engage he felt very certain that supravaginal delivery was a safer procedure, in the interest of the child, than any intravaginal method. A large number of children delivered by the latter procedure died later from cerebral compression. He added his protest to the Scanzoni method.

Dr. CAREY of Chicago said the relative size of the head must be taken into consideration. There was a great deal of difference. There was nothing very terrible in going up and changing the position of the head that had become fixed posteriorly into an occipitoanterior position. When once converted into this position it must be left so. Where the baby was dead, by holding the head with vulsellum forceps for a while it would come down without further difficulty.

The Policy of Noninterference in the Treatment of Postabortive and Puerperal Infections.—Dr. EDWARD L. KING of New Orleans based this report on several hundred cases which had been treated in the Charity Hospital of New Orleans, where for five years a special ward had been set aside for the handling of cases of infections on the white obstetric service. Operative procedures had been limited to the drainage of definitely established and easily accessible pus collections. No patients requiring major operations were admitted to the ward, with the exception of an occasional one who required the "rest treatment" before operation. The temptation, therefore, to operate on unprepared cases, in order to increase the "turnover" of operative work, had been eliminated. The mortality following the plan of treatment had been very low, and the results, with reference to the ultimate condition of the pelvic organs, had been most gratifying.

Dr. JOHN OSBORN POLAK of Brooklyn, N. Y., agreed with the essayist with regard to the wisdom of expectancy, and yet there were cases in which a little judicious intervention was needed. Fowler's position to facilitate drainage, turning the patient on the side from time to time, and repeated small transfusions with citrated blood in cases of bacteriemia, were some of the measures mentioned.

Dr. KING, in closing the discussion, thought Fowler's position did good, but in two fatal cases autopsy

showed nothing with regard to this matter. He had not tried repeated small transfusions. He had tried one large transfusion, but without benefit.

The Management of Acute Appendicitis in the Later Weeks of Pregnancy. Report of a Case Treated by Cesarean Section and Appendectomy.—Dr. JAMES M. MASON of Birmingham, Ala., based this paper on a case of appendicitis developing within the last three weeks of pregnancy. The woman, a primagravida, was due to be confined in the latter part of January, 1920. She had had previous attacks of slight indigestion, suggesting appendicitis. She had had an attack of toxemia, manifested by an attack of nausea accompanied by casts in the urine. She had recovered after ten days in bed. Early in January she was awakened in the night by pain, nausea and vomiting, the pains being over the lower abdomen. Uterine contractions could be seen and felt. There was no tenderness over the abdomen. The urine showed a few hyaline casts, no albumin. Vomiting continued through the day, and the temperature and pulse were high. The symptoms persisted during the next day. Vaginal examination showed the head low down in the pelvis. Continued vomiting and high leucocyte count, together with pain in the right iliac fossa led to the diagnosis of appendicitis. Cesarean section was performed, under gas-oxygen anesthesia, sixty-six hours after the onset. The fetus was extracted, the abdominal incision retracted the appendix, acutely inflamed, was located low down in the pelvis, and appendectomy was performed, followed by uneventful recovery. The high mortality attributed to appendicitis during pregnancy was due to failure to recognize the condition and to treat it along well recognized lines. Appendicitis occurring during the later stages of pregnancy called for immediate operation, prompt interference being demanded as soon as the diagnosis was made. In making the diagnosis some time must inevitably be lost in determining the cause of the pain. Repeated observations must be made, and the tendency of pain to be referred to the iliac fossa must be given due weight. Severe persistent pain called for operation, which might be exploratory in some cases. At this late stage the child was in no danger from the termination of the pregnancy. The question immediately arose as to whether one should terminate the pregnancy first or remove the appendix. The essayist advocated terminating labor first and performing appendectomy afterward, the danger of the spread of infection to all parts of the abdominal cavity being thus lessened. Pregnancy under these circumstances should be terminated by no slow and uncertain method. Cesarean section seemed best to meet these requirements, but each case should receive careful individual consideration before deciding upon a plan of treatment.

Dr. A. H. CURTIS of Chicago said that occasionally a diseased appendix must be removed irrespective of the stage of pregnancy. Not only should the appendix be removed in acute cases, but in every case, as one never could tell when complications might arise. He used novocain local anesthesia in such cases. The existence of a diseased appendix called for especial care in the closure of the abdominal wound. He used strong ligatures, making a figure-of-eight suture, so that there would be no hernia when the fetus was delivered through the normal channel.

Dr. FRANCIS LE S. REDER of St. Louis, Mo., thought it would be a good thing if women were instructed to have themselves thoroughly overhauled before subjecting themselves to conception, and in case of an attack of appendicitis, to have the appendix removed during the interval. Up to the fourth month of pregnancy the diseased appendix could be removed with comparative safety; from the fourth to the seventh month this safety became a danger; but from the seventh month on pregnancy complicated by appendicitis called for the exercise of careful judgment in the management of the case. It had been his observation that appendicitis in the seventh month or later did not show the same virulency as in the earlier cases, and in some cases in which the recommended operation had been refused the woman had gone on without trouble. Should the condition be such, however, as to make it extremely unsafe for the patient to go on without intervention, what course should be followed? He was inclined not be to hasty, but to study the condition, and as long as it remained within the limit of safety not to resort to surgical interference. Should the condition go on to suppuration, a puncture, not through the vagina but through the rectum, and evacuation of the pus would sometimes suffice, without disturbing the pregnant uterus. The risk of operation for a pregnant woman at seven months or later was extremely great. The wound would, through the stress and strain of the abdominal distention, probably break down and become infected. As to cesarean section, he considered it a great risk, a severe step to take.

Dr. DAVID ROSS of Indianapolis thought the question of the advisability of operating at any given time in appendicitis complicating pregnancy was a matter of individual judgment. If there were any definite means of telling that the appendix would go on to suppuration and rupture, all would choose operation, but little could be foretold as to what would be the outcome. The thing that had impressed him most in the paper was the suggestion of cesarean section in the face of such infection. He would not subject any woman to this operation in the presence of a ruptured appendix.

Dr. MASON, in closing the discussion, emphasized the opinion that a pregnant woman with appendicitis, in no matter what stage of the pregnancy, was in a dangerous condition, not because of the pregnancy but because of the appendicitis. No one could tell which case would go on to rupture and which would get well, hence he advocated the surgical principle that appendicitis should be operated early. Cesarean section, with the present-day technique, was an exceedingly simple operation, and much safer than removing the appendix and leaving the uterus intact, with the danger of labor coming on and the possibility of peritonitis. Extraperitoneal cesarean section under gas-oxygen anesthesia seemed to him the safer course.

Third Day—Friday, April 30.

An Operation for Pruritus of the Vulva and Anus.—Dr. CARROLL W. ALLEN of New Orleans contributed this paper, which, in the author's absence, was read by Dr. E. Denegre Martin of New Orleans. The technique was described of an operation the object of which was to divide all nerve filaments to the affected parts, thereby preventing all painful or itching sensations. The skin or mucous membrane of the affected area was separated from the underlying tissue by a series of incisions. The course, direction and general plan of these incisions varied with the parts involoved, but as a rule they were made to radiate from the center outward. The strips of skin thus made were dissected up from the underlying tissues, but were left attached at their two ends. The space beneath was packed with iodoform gauze to prevent immediate union. The pack might need to be changed occasionally, but generally remained in place one week. After granulations become established the packing was removed. The total disability was generally about two weeks. Relief was permanent.

Dr. E. DENEGRE MARTIN of New Orleans thought soap and water would be useful in these cases, especially in the very common milder cases. In those operated upon he doubted whether the results were permanent, and thought it would be advantageous to find some method of treatment in which confidence could be placed.

Prolapse of the Urethra in the Female. (Lantern Demonstration.)—Dr. RICHARD R. SMITH of Grand Rapids, Mich., presented this paper for the purpose of calling attention to this condition, to describe it, and to offer simple means for its correction. So-called bladder symptoms were among the most annoying that arose from childbirth injury, and were due partly if not entirely to loss of the structures anterior to the vagina which supported the bladder and urethra. Far more attention had been given to the perineal tear than to the results of these anterior defects. It was difficult to understand why this oversight was of such common occurrence. It was only recently that cystocele had received the attention it deserved. When a woman complained of urinary retention or other symptoms traceable to the bladder a systematic examination of the bladder and upper urinary tract should be made in terms of infection, and mechanical defects should be

looked for. If one found a cystocele the examination should not stop here; due consideration should be given to the integrity of the posterior and anterior vaginal walls. The meatus urinarius should not be overlooked, as was so apt to be the case. With the patient on the back this would protrude but little; but if the woman were asked to strain, if there had been injury to this region the meatus and the anterior vaginal wall would roll forward. The condition of the meatus was most important. The mucosa at the lower end of the urethra rolled out of the meatus, exposing the body of the anterior canal. It would be found to have two small lips, torn and stretched, forming very imperfect protection to the mucosa within. The mucosa was often the sort of caruncule. If one asked such a patient, up and about, if she experienced discomfort in this region, she would answer in the affirmative. Clothing and bathing irritated the parts. Practically all her symptoms might be those mentioned. Frequency of urination had many causes, the trouble usually being located in the urinary tract above the meatus, but it might be below. The passage of urine over a swollen and irritated meatus produced burning and irritation. In considering cystocele it was important to see if the urethra was prolapsed. Operation for the correction of prolapse of the urethra would vary according to the circumstances. Caruncule or protruding mucosa must be removed, this being done very carefully. Very fine stitches might occasionally be necessary. Closure of the meatus usually was all that was necessary. This was accomplished by a very simple procedure, which varied more or less according to the case. The details of the operation were shown by means of lantern slides.

Dr. S. M. D. CLARK of New Orleans considered the condition under discussion an important one, causing untold annoyance to those afflicted with it. Many procedures had been devised for its correction. He was working along this line in 1913, when one of his associates reviewed a paper by Murette of Paris, who held that the walls of the urethra are parallel, and that the external urethra had very little to do with the control of urine. In childbirth, when the structures which supported the anterior vaginal wall were injured, instead of this parallel condition of the walls of the urethra, this canal became funnel-shaped. Murette had devised a procedure for the restoration of the parallel relationship of these walls. The speaker had employed this operation in his clinic with satisfactory results. In the removal of caruncule and hypertrophied mucous membrane he had found the Paquelin cautery very useful.

Dr. A. H. CURTIS of Chicago called attention to the importance of examining these patients in the standing position. With the patient lying down it was easy to overlook relaxation of the urethra or even prolapse of the uterus. The most frequent type of urethral caruncle was found with a moderate prolapse of the urethra with redundancy of granulations on this prolapsed tissue. Corrective measures involved not merely the removal of the caruncle but a reparative operation for the prolapse of the urethra and cystocele. If this were done there would be no recurrence.

Dr. SMITH, in closing the discussion, said he had purposely omitted the discussion of cases of incontinence, because the operation which he described was insufficient in these cases. He had purposely, also, omitted operations for cystocele. Dr. Curtis' suggestion with reference to examining the patient in the standing position was a good one. He agreed with this speaker with regard to recurrence of caruncle after merely snipping it off. The mucous membrane must be protected by making a denudation, then bringing the surface well up out of the way.

Cysts of the Pancreas (Lantern Demonstration).—Dr. JOHN J GILBRIDE of Philadelphia, Pa., presented this demonstration of the different varieties of cysts associated with the pancreas. Many cysts supposed to be cysts of the pancreas were not true pancreatic cysts. The fact that a cyst appeared to be connected with the pancreas did not establish its pancreatic origin. The cysts of the pancreas were due to obstructed duct and retention of fluid—so-called retention cysts. There were also proliferation cysts, due to proliferation of the structures of the gland, which included cystic adenoma and carcinoma. Hydatid cysts of the pancreas were occasionally encountered, and the gland sometimes became involved in a general cystic condition. Hemorrhagic cysts were due to trauma, but the presence of blood in a cyst was no indication of this origin, as it might be due to erosion. The great majority of cysts encountered by the surgeon and reported in the literature were so-called pseudo-cysts. It was difficult to determine whether a cyst was a true cyst or a pseudo-cyst. Nicholas Senn had said that it would be impossible for a cyst to originate in the pancreas, as the gland would absorb the secretion. Proliferation cysts, however, arise as true pancreatic cysts. Pseudo-cysts were due to the accumulation of pancreatic secretion of an abnormal character. Many factors had been suggested as concerned, among them the presence of gallstones, chronic pancreatitis, and fibrous tissue formation. Cystic tumors might be situated in any portion of the gland; they might be unilater or bilater, unilocular or multilocular, and a number of small cysts might be found in the larger cyst. True pancreatic cysts were usually lined by a flattened layer of cylindrical epithelium, which frequently disappeared. Pseudo-cysts were never lined by epithelium, their walls being always formed of connective tissue. Pseudo-cysts and cysts were often found in the same patient. The origin of cysts in the neighborhood of the pancreas had not received sufficient study, and in most instances the fluid contents of the cyst had not received careful examination. Little information as to the origin of the cyst was furnished by its contents, but the detection of ferments in it was of diagnostic significance. The symptoms were frequently referable to disturbances of digestion, flatulence and distress after eating, pain, burning in character, sometimes colicky, nausea and vomiting, sometimes diarrhea, being among the symptoms noted. Blood might be found in the gastric contents, in the feces, or in both. There might be dilatation of the superficial veins of the abdomen. Some patients lost a great deal in weight, giving rise to the suggestion of malignancy. When jaundice occurred the cyst was located in the head of the gland. The cyst was usually spherical and smooth. Its position might be in the median line, between the ensiform cartilage and the umbilicus, the most common location being between the stomach and the transverse colon. It might project below the transverse colon, pushing the colon with it. The part of the gland most frequently involved was the tail. Treatment involved exposure of the cyst, examination in relation to surrounding structures, drainage and fixation to the abdominal wall; exposure, fixation and subsequent opening and clearing out; or extirpation. Aspiration had been suggested, but should not be used except for drainage. Some surgeons opened anteriorly and made a counter opening posteriorly, but drainage anteriorly was quite sufficient. The injection of chemicals into the cyst should not be done.

Dr. MOSES BEHREND of Philadelphia, Pa., classified cysts of the pancreas as acute and chronic, the acute being those operated upon within the first week, the chronic those which had been in existence many months and even years. It was not necessary to remove these cysts, but sew the cyst wall to the parietal peritoneum, pack with gauze, and leave the gauze in for at least eight days.

Dr. HARTWIG of Los Angeles, Cal., said if there were no glands in the syst wall the cyst could be emptied by the simple procedure of introducing a catheter fitted into an ordinary trocar, smearing the catheter with vaseline so that it would pass in easily, yet fit, and withdrawing the tube of trocar while pushing in the catheter.

An Improved Technique for Cholecystectomy Based on an Anatomical Study. (Lantern Demonstration.)—Dr. MOSES BEHREND of Philadelphia, Pa., described this technique by means of lantern slides, first reviewing the history of cholecystectomy. Some surgeons had performed the operation without strict regard to the anatomy of the gall-bladder and its ducts. The closed method of operation, the ligation of the cystic duct by what he called the "hit or miss" method within the gastrohepatic omentum, might result in injuries to the common duct, the hepatic duct and the hepatic artery. The ligation of the cystic duct at an improper level might result in leaving too much or too little

of the cystic duct. By the method which he employed each step in the procedure was visualized. With the patient in a suitable position, he operated from below upward, opening the right free border of the gastrohepatic omentum, which made it possible to see all the structures. The many variations in anatomical arrangement of the structures involved were illustrated by lantern slides to further emphasize the possibilities for danger in the closed method of performing cholecystectomy. These studies were based on the examination of one hundred and sixty-seven cases.

Dr. ALFRED C. WOOD of Philadelphia, Pa., considered his operation very important as affording an opportunity to see every step of the procedure. The many variations in the relationship and arrangement of the cystic duct and cystic artery, as shown in the slides, furnished ample justification for this method in contradistinction to the closed operation. The duct and artery should not be ligated together. The operation, however, was not quite as simple a procedure in practice as in illustration, especially in a stout patient. The ducts were very deep and hard to find, and the patient should be properly posed. It made little difference whether one did or did not cover the stump, provided there was no bleeding. He had seldom found it necessary to drain. This plan of performing cholecystectomy was followed by rapid recovery and perfect health. In some cases of long standing it was not possible to do an ideal operation. When inflammatory conditions had so changed the anatomical relations that he could not follow the essayist's plan, he sometimes proceeded from below upward.

Dr. HAEBERLIN of Chicago considered the crucial point of the technique getting sufficient exposure to know what one was doing. However, in some cases it was advisable to operate from above downward. Closure by primary union was the ideal method.

Dr. SEIFERT of Chicago emphasized the importance of severing the gall-bladder as near to its origin as possible, otherwise the stump would take the place of the gall-bladder and stones would form.

Dr. JOHN J. GILBRIDE of Philadelphia said in ordinary cases of cholecystectomy one would encounter no difficulty, but in other cases one could not be too cautious. He cited the case of a woman operated upon for removal of the gall-bladder, who would not remain in the hospital, but went home before the wound had closed. She was placed under the care of another physician who dressed the wound. A short time afterward she developed fever, became profoundly jaundiced and had all the symptoms of infection. She returned to the hospital, very much perturbed about her condition. He waited until he obtained a specimen of her feces, which he examined himself, and found bile in the feces. Roentgen examination was negative as to gallstones.

Dr. QUAIN of Bismark, N. D., had used for the last few years a transverse incision for gall-bladder exposure instead of the longitudinal or oblique. It was more logical from an anatomical point of view. The arrangement of the skin indicated such an incision, which left practically no scar, whereas the longitudinal or oblique incision always left a scar. The deeper structures, likewise, were arranged longitudinally, and in closing the tissues simply fell together. The abdominal wall was supplied by the intercostal nerves, which were destroyed in the majority of instances, meaning a weakening of the abdominal wall inside of the incision, rendering the patient more liable to hernia. The peritoneum was also supplied by the intercostals, and destruction of the nerve supply rendered more probable the formation of peritoneal adhesions. The blood supply was from the deep epigastric which anastomosed with the mammary; the transverse incision gave the best opportunity for reconstruction of the blood supply. The rectus muscle was cut across, but that was the least important abdominal structure because it healed without trouble. Exposure was along the line of the common duct, which could be examined more easily. The stomach, too, could be examined more easily. In thirty per cent. of cases in which he made the transverse incision for gall-bladder disease the appendix could be removed. The patient was more comfortable after the transverse incision than with the longitudinal or oblique.

Dr. RICHTER of Chicago was inclined to believe that the anomalies of which the essayist had given such interesting illustrations were of no great importance. They should be seen and dealt with as one went along. He agreed that the stump might form gallstones, necessitating re-operation. It was not necessary to suture the surfaces left by removal of the gall-bladder. The gall-bladder practically always occupied a depression, and when it was pulled out of the depression little flaps of tissue would cover it. Adhesions found in gall-bladder surgery were due much more to packing and drainage than to leaving raw surfaces. In practically all cases the wound could be closed without drainage.

Dr. DEHREND, in closing the discussion, agreed with Dr. Wood that the cystic duct and artery should be ligated separately, not together. It made no difference how many adhesions there were, there would be no trouble if one opened gastrohepatic omentum. The time required for the operation was from five to twelve minutes from the making of the incision to its closure. The gravity of the operation was no greater than that of appendectomy. One must know, however, how to use the left hand, and how to use retractors and sponges in the abdomen. The operation could be done from below upward very much more easily than from above downward. He took issue with Dr. Richter regarding the importance of the anomalies shown in the slides. He considered them of tremendous importance. Knowledge of them would prevent injury to the common duct and the hepatic duct.

Appendicitis Caused by Ameba Dysenteriæ. Post operative Perforation of an Amebic Ulcer of the Cecum. (Lantern Demonstration.)—Dr. EDGAR P. HOGAN of Birmingham, Ala., based this paper on the report of a case and a review of the literature. The patient was a negro man, thirty-three years of age, resident of Birmingham, Ala. He did not remember ever having had diarrhea. Three days before he was seen by the essayist he became suddenly ill, with pain in the abdominal region, later localized in the lower right quadrant. He was fairly well nourished, had a temperature of 101°, pulse of 90, heart and lungs were normal. Pressure over McBurney's point elicited intense pain. The leucocyte count was high. The diagnosis of appendicitis was made, and the appendix was removed through a right rectus incision. The appendix was long and in an inflammatory condition. The case seemed to be one of typical acute appendicitis, and the convalescence progressed in an apparently normal manner for five days, then blood appeared in the stools, repeated intestinal hemorrhages occurred, the patient grew worse, and died on the seventh day. Autopsy revealed general peritonitis due to a ruptured cecal ulcer, with other ulcerative lesions in the cecum and proximal colon. The pathological findings indicated the presence of *Endameba hystolytica*. From the study of this case it was concluded that intestinal amebiasis might be present without symptoms of diarrhea or dysentery; that *Endameba hystolytica* might invade the appendix, producing typical symptoms of appendicitis; that every appendix removed should be examined and the cause of disease established; and in case of death autopsy should be secured.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NERRASKA STATE BOARD OF MEDICAL EXAMINERS.

November, 1919.

ANATOMY.

1. Draw the proximal one-third of the femur, including the head and neck, indicating the attachment of muscles.
2. Draw the dorsal surface of the bones of the tarsus, and name the bones.
3. Describe the shoulder joint, and name the ligaments of the shoulder joint.
4. Describe the biceps muscle.
5. Describe the deep palmar fascia.

6. Give plan or describe the relations of the common carotid artery.
7. Name the branches of the facial artery.
8. Name the branches of abdominal aorta.
9. The Gasserian ganglion is made up in the main from what nerve? Name the three large branches of the ganglion.
10. Give the length and relations of the first portion of the duodenum.

PHYSIOLOGY.

1. What is the function of the nose in respiration? What are the causes and effects of mouth breathing?
2. Describe (a) living tissue, (b) dead tissue, (c) and metabolism.
3. Describe and give function of the cerebellum.
4. Describe (a) chyme, (b) chyle.
5. Name the three most important groups of food stuffs that produce muscular energy.
6. What is the normal amount of blood in the body? How restored after hemorrhage?
7. Give the physiology of (a) hunger, (b) thirst.
8. What is meant by reflex action? Give its physiological circuit.
9. Describe the pulse. What factors influence it? What is the normal pulse rate in (a) infancy, (b) youth, and (c) age?
10. Name five digestive secretions. How does each affect the food?

CHEMISTRY.

1. (a) Differentiate between physical and chemical phenomena. (b) Give examples of each.
2. What is an element? (b) A compound? Give an example of each.
3. Name 10 elements found in the human body.
4. What is a mixture? Give an example of two physical and two chemical mixtures.
5. What is a monad? Dyad? Triad? Tetrad? Pentad? Give an example of each.
6. Give symbol, valence, atomic, and molecular weights of hydrogen, oxygen, sulphur, mercury, gold, nitric acid, and sulphuric acid.
7. What is the meaning of the terms (a) formula, (b) equation, (c) reaction, (d) function? Give an example of each.
8. What are the post-mortem appearances of acute phosphorus poisoning?
9. What are the common names of As_2O_3? $HgCl_2$? Do they have any toxic properties?
10. What is glycogen? Where found? Test for same?

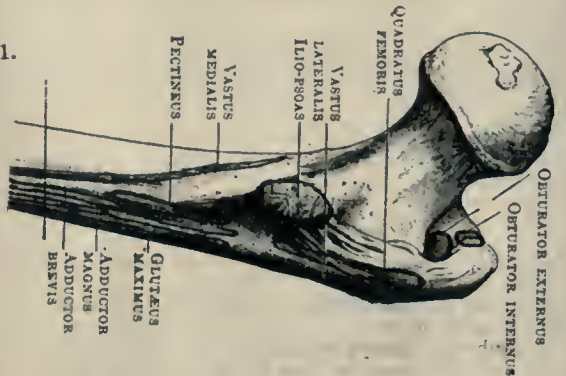
PATHOLOGY.

1. (a) What tissues of the intestinal canal are most commonly affected in typhoid fever? (b) What four stages characterize the pathological process in these tissues?
2. Differentiate microscopically hypertrophic endometritis from adenocarcinoma of the uterus.
3. Describe the modus operandi of focal infection.
4. Discuss the pathological process of infection in acute appendicitis to the point of perforation.
5. Describe the microscopical picture of a tubercle in tuberculosis.

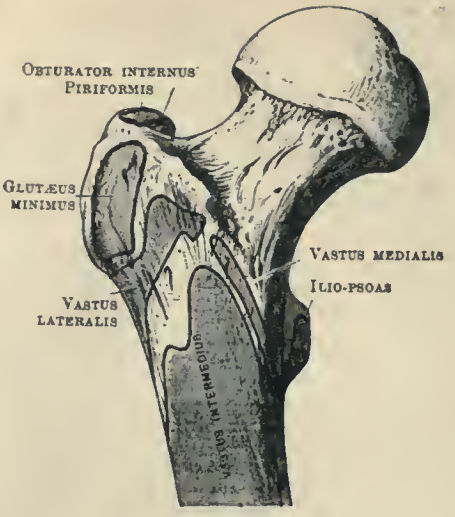
ANSWERS.

ANATOMY.

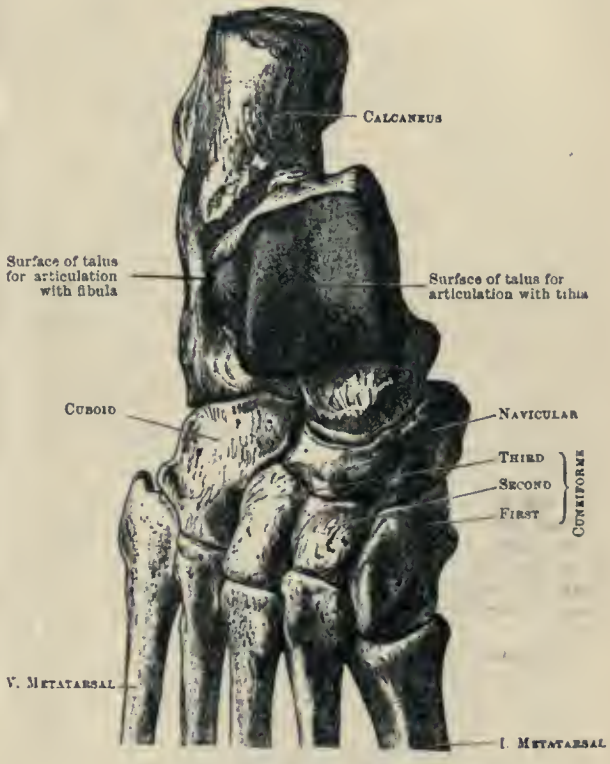
1.



(From Cunningham's *Anatomy*.)



2.



(From Cunningham's *Anatomy*.)

3. The *shoulder-joint* is an enarthrodial joint formed above by the glenoid cavity of the scapula and below by the head of the humerus. Its ligaments are glenoid, coraco-humeral, and capsular. The glenoid surrounds the edge, deepens the glenoid cavity, and is continuous above with the long head of the biceps tendon. The capsular ligament, extensive and loose, arises above it from circumference of glenoid cavity behind the ligament, is attached below to the anatomical neck of humerus, and is pierced by tendons of two or three muscles. The coraco-humeral, or accessory, is a fibrous band which extends obliquely downward and outward from the coracoid process to the anterior part of great tuberosity, strengthening the capsular ligament. A *synovial membrane* lines the joint, and forms the bursa under the subscapularis. It is reflected round the tendon of the biceps, and lines the bicipital groove. The *nerve supply* is from the circumflex and suprascapular nerves. The *arteries* are branches of the anterior and posterior circumflex, and the suprascapular.

The *muscles in relation with the joint* are: above, the supraspinatus; below, the long head of the triceps;

in front, the subscapularis; behind, the infraspinatus and teres minor; internally, the long head of the biceps. The deltoid covers the joint in front, behind, and externally.

4. The *Biceps branchii* lies over the anterior surface of the arm. It arises by two heads: (1) From the coracoid process of the scapula, and (2) from the upper margin of the glenoid cavity of the scapula. It is inserted into the back part of the tuberosity of the radius. The muscle is overlapped in its upper part by the deltoid and pectoralis major; its inner border is in relation with the coracobrachialis, and its outer border with the deltoid and brachialis anticus. It is a flexor and supinator of the forearm, and it is supplied by the musculocutaneous nerve.

5. The *deep palmar fascia* is situated in the palm of the hand, and consists of a central portion and two lateral portions. The central part is triangular in shape, being narrow above, where it is attached to the anterior annular ligament and receives the tendon of the palmaris longus; below, it expands at the roots of the fingers and is connected with the sheaths of the flexor tendons. Opposite the heads of the metacarpal bones it splits into four parts, and each of these parts is prolonged on to the sheath of one of the flexor tendons. The fascia is closely adherent to the skin of the palm, and it covers the superficial palmar arch, the tendons of the flexor muscles of the fingers, and branches of the ulnar and median nerves. The lateral portions of the fascia are much thinner, and cover the muscles of the thumb and little finger.

6. *Relations of the common carotid artery.* The artery, together with the internal jugular vein and vagus nerve, is included in a common sheath derived from the deep cervical fascia; in the sheath the artery is the most internal, the vein most external, and the nerve behind and between. The chief relations of the sheath to the surrounding parts are the following: As high as the cricoid cartilage it is deeply placed, and is *covered* by: (1) The common investments (*i.e.*, skin, superficial fascia, platysma and deep fascia). (2) Sternal head of sternomastoid. (3) Sternohyoid. (4) Sternothyroid. (5) Crossed by omohyoid. (6) Above this point it enters the carotid triangle, is covered by the common investments of the parts overlapped by the sternomastoid, and crossed by the sternomastoid artery. (7) It is also crossed by superior thyroid, middle thyroid and anterior jugular veins. (8) The descendens hypoglossi lies *on* (rarely *in*) the sheath. (9) In front of the superficial part there are some lymphatic glands. *Behind* the sheath are: (1) The gangliated cord of the sympathetic. (2) The recurrent laryngeal nerve crossing obliquely inwards behind the sheath. (3) Longus colli. (4) Rectus capitis anticus major, and behind these (5) the transverse processes of the cervical vertebræ. (6) The inferior thyroid artery also crosses obliquely inwards behind both the sheath and the gangliated cord of the sympathetic. (7) Behind the deep part of the sheath are some lymphatic glands. To its *inner side* we have: (1) The larynx and trachea. (2) Pharynx and esophagus. (3) Thyroid body. (4) Recurrent laryngeal nerve, and inferior thyroid artery. To the *outer side* a chain of lymphatic glands, and the scalenus anticus.—(From McLachlan and Skirving's *Applied Anatomy.*)

7. *The branches of the facial artery* are: Ascending palatine, tonsillar, submaxillary, submental, inferior labial, inferior coronary, superior coronary, lateral nasal, angular, and muscular.

8. *The branches of the abdominal aorta* are: Phrenic, celiac axis, superior mesenteric, inferior mesenteric, suprarenal, renal, spermatic, or ovarian, lumbar, and middle sacral.

9. The *Gasserian ganglion is made up mainly* of the fibers of the trigeminal, or fifth cranial nerve. The *three large branches of the ganglion,* are: Ophthalmic, superior maxillary, and inferior maxillary.

10. *The first portion of the duodenum* is about two inches in length. It is *in relation—above* and *in front* with the quadrate lobe of the liver, and the gall bladder; *behind,* with the common bile duct, portal vein. and gastroduodenal artery; *below,* with the head of the pancreas.

PHYSIOLOGY.

1. *The function of the nose in respiration,* is : (1) To warm the air; (2) to saturate it with moisture, and (3) to prevent the entrance into the lungs of foreign particles (these are filtered out by the vibrissæ).

Mouth-breathing may be caused by: Obstruction of the nasal passages from tumors, foreign bodies, fracture of the turbinate or nasal bones, hemorrhage, catarrh with thick secretions, hyperemic conditions of the mucous membranes, deflection of the septum, hypertrophy of the turbinate bones, adenoids in the nasopharynx, and hypertrophied tonsils.

Effects of mouth-breathing: The entrance or exit of the air is impeded; the inspired air is not warmed, not moistened, and not filtered; dyspnea; hoarseness; twang to the voice; dryness of mouth and tongue; snoring; fetid breath.

2. *Tissue* consists of a collection of cells of similar character, united for the performance of a special function. These cells are generally united by intercellular substance, and supported by connective tissue. *Living tissues* are capable of performing some function. *Dead tissues* are not capable of performing function.

Metabolism is the name given to the collective changes which are continually occurring in the living body; the changes concerned in the upbuilding of the body and its tissues and cells are called *anabolic* changes; those which are due to the wasting of the tissues are called *catabolic* changes.

3. The *cerebellum* is the largest portion of the hindbrain. It lies in the posterior fossa of the skull, separated from the occipital lobes of the cerebrum by the tentorium cerebelli. It is behind the pons and medulla oblongata, connected with the former through the middle peduncles, and partly embracing the latter; and connected with the restiform body by means of the inferior peduncles; the superior peduncles contain fibers which pass from the cerebellum to the tegmentum of the midbrain, ventrad of the inferior corpora quadrigemina, the latter bundle of fibers pass to the red nucleus of the opposite side, some continue to enter the thalamus. The cerebellum is divided into a medial segment, the *vermis,* or *worm;* two *lateral hemispheres;* a *ventral* and *dorsal notch;* and a superior and inferior surface; and is subdivided into lobes and fissures.—(Little's *Anatomy.*)

The *cerebellum* is about 3½ to 4 inches transversely, 2 to 2½ inches anteroposteriorly, and about 2 inches thick in the center; it weighs about 5½ ounces, and its proportion to the cerebrum is about 1:8.

The *functions of the cerebellum* are: Co-ordination of muscular movements, maintenance of equilibrium, and muscle tonus.

If the cerebellum is removed there is a lack of co-ordination, and loss of equilibrium; but sensation in general is not affected.

4. *Chyme* is a thick, acid liquid, which is the result of gastric digestion; it consists of proteids, salts, liquefied fat, and undigested matter. It is passed forward into the duodenum.

Chyle is that portion of the lymph which is found in the small intestine during the period of digestion; it is mainly composed of water, proteids, and fats, the latter giving it a milky appearance.

5. *The three most important groups of foodstuffs that produce muscular energy* are: Proteins, carbohydrates, and fats.

6. The total quantity of blood was formerly said to be about one-thirteenth of the weight of the body; recently this figure has been altered to one-twentieth of the body weight.

Regeneration of blood after a hemorrhage: "If the bleeding does not go on to death the blood is restored by absorption from the tissues or from the food taken in; the first to be absorbed being the serum sanguinis, with the dissolved salts, and then the albumen. A longer time is required to form new red blood-corpuscles. Regenerated blood is at first abnormally watery and poor in cells. As a result of the greater flow of lymph into the blood the number of white blood-corpuscles is greatly increased, and then their number falls off; the red blood-corpuscles again attain their usual number, and the composition of the blood grad-

ually returns to the normal. We do not as yet know certainly how the restoration of the red blood-corpuscles takes place. The most generally accepted view is that colorless corpuscles are being constantly formed in the lymph glands, in the spleen, in the bone marrow, and in the liver, and a certain number of these colorless corpuscles change into the red disks."—(Tillmann's *Surgery.*)

7. *The sensation of hunger* is referred to the region of the stomach, and is the outcome of nervous impulses from the stomach. *The sensation of thirst* is located in the back of the pharynx. Both of these sensations are localized expressions of a general need of the tissues of the body for food and drink. The exact seat of the sensations is unknown; and thirst is more painful and more urgent than hunger.

8. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

9. The pulse is the impulse conveyed to the column of blood in the arteries by the contraction of the ventricles and the propulsion of more blood into the already full arterial system. The characters of the pulse which are of most importance are its force, frequency, length, rhythm, and tension. It is maintained by the ventricular systole, the elasticity of the arterial walls, and the volume of the blood in the vessels. The points to be observed are: (1) Its *frequency;* this gives the rate of the heart beats. (2) Its *compressibility;* this denotes the force with which the heart is beating. (3) Its *tension;* this denotes the peripheral resistance, and also the state of the arterial walls. (4) Its *regularity* or *rhythm;* this denotes the regularity (or otherwise) of the heart's action in force or rhythm. The average rate during infancy is about 120 per minute; during youth, about 80; and during old age, about 60. The normal ratio of pulse to respiration is about 4:1.

10. *Five digestive secretions:* Saliva, gastric juice, pancreatic juice, succus entericus, and bile.

Effect of saliva on food: Saliva assists in the solution of the soluble portions of the food; it assists the sense of taste; it lubricates the bolus of food and so aids mastication and deglutition; it changes starches into sugar.

Effect of gastric juice on food: It changes proteins into proteoses and peptones and sometimes into polypeptides; it curdles the casein of milk.

Effect of pancreatic juice on food: It converts proteins into proteoses and peptones and then into polypeptides and amino-acids; it converts starches into maltose; it emulsifies and saponifies fats; it curdles the casein of milk.

Effect of succus entericus on food: It converts starch into detrin and then into dextrose and levulose; it also splits polypeptides into amino-acids and ammonium compounds; it converts sugars into dextrose, levulose, and galactose.

Effect of bile on food: It assists in the emulsification and saponification of fats; it aids in the absorption of fats; it has a slight action in converting starch into sugar.

CHEMISTRY.

1. If a bar of soft iron be heated sufficiently it becomes luminous; if caused to vibrate it emits sound; if introduced within a coil of wire through which a galvanic current is passing, it becomes magnetic and attracts other iron brought near it. Under all these circumstances the iron is still iron, and so soon as the heat, vibration, or galvanic current ceases, it will be found with its original characters unchanged; it has suffered no change in *composition.* If now the iron be heated in an atmosphere of oxygen gas, it burns, and is converted into a substance which, although it contains iron, has neither the appearance nor the properties of that metal. The iron and a part of the oxygen have disappeared, and have been converted into a new substance, differing from either; there has been change in *composition,* there has been *chemical action.* Changes wrought in matter by physical forces, such as light, heat, and electricity, are temporary, and last only so long as the force is active; except in the case of changes in the state of aggregation, as when a substance is pulverized or fashioned into given shape. Changes in chemical composition are permanent, lasting until some other change is brought about by another manifestation of chemical action. While chemical action is thus different in its results from the actions of physical forces, there exists the most intimate relation between them. As above stated, they are interconvertible. The line of demarcation between chemical actions and certain physical actions, such as solution, although distinct, is narrow. Many chemical actions take place only under certain physical conditions, such as of temperature; or are provoked by physical forces, such as light.—(From Witthaus' *Chemistry.*)

2. An *element* is a kind of substance out of which we cannot get anything else, as hydrogen.

A *compound* is a substance made up of two or more elements, chemically united, in definite proportions, as sulphuric acid, H_2SO_4.

3. *Ten elements found in the human body:* Carbon, hydrogen, oxygen, nitrogen, sulphur, phosphorus, calcium, sodium, potassium, iron.

4. A *mixture* is a union of two or more substances (elements or compounds) in any proportion, and without chemical union. *Two physical mixtures:* (1) Iron filings and sulphur; (2) sand and sugar. *Two chemical mixtures:* (1) Iron filings and sulphur, heated; (2) tartaric acid, sodium carbonate and water.

5. A *Monad* is an element having a valence of one, as hydrogen.

A *Dyad* is an element having a valence of two, as oxygen.

A *Triad* is an element having a valence of three, as boron.

A *Tetrad* is an element having a valence of four, as carbon.

A *Pentad* is an element having a valence of five, as phosphorus.

6.

	SYMBOL	VALENCE	ATOMIC WEIGHT	MOLECULAR WEIGHT
Hydrogen	H	1	1	2
Oxygen	O	2	16	32
Sulphur	S	2 or 6	32	64
Mercury	Hg	1 or 2	200	200
Gold	Au	1 or 3	197	394
Nitric acid	...	....	...	63
Sulphuric acid	...	....	...	98

7. *Formula* is an abbreviation which shows the number and kind of atoms of which the molecule of a compound is composed. HNO_3 is formula for nitric acid.

Equation is a combination of formulæ and algebraic signs so arranged as to indicate a chemical reaction and its results. Thus:

$$2KOH + H_2SO_4 = K_2SO_4 + 2H_2O$$

Reaction denotes the mutual action of two or more substances on each other, as in the equation just given.

Function is the chemical character and relationship of a substance, and indicates certain general properties, reactions, and decompositions which belong to all substances having the same function. Thus it is a "function" of a primary alcohol that it contains the hydroxyl group (OH), and that on oxidation it becomes first an aldehyde and then an acid.

8. *Post-mortem appearances of acute phosphorus poisoning:* "Occasionally small fragments of phosphorus may be detected, by their luminous appearance, in the stomach or intestines. The esophagus, stomach, and intestines are frequently marked with ecchymotic spots. Advanced fatty degeneration is observed in the liver, kidneys, heart, and muscular tissue. The blood is very fluid, and the red corpuscles more transparent

than normal."—(*Essentials of Chemistry and Toxicology.*)

9. The common name of As_2O_3 is white arsenic; it certainly has toxic properties. The common name of $HgCl_2$ is corrosive sublimate; it certainly has toxic properties.

10. *Glycogen* is a polysaccharide with the empirical formula $n(C_6H_{10}O_5)$. It occurs in the liver, placenta, white blood corpuscles, pus cells, cartilage, and muscle. Glycogen is colored red by iodine.

PATHOLOGY.

1. *Pathology of typhoid fever.*—"Principally inflammation of the lymphoid tissue of the lower portion of the ileum, with more or less catarrh throughout the bowels. Peyer's Patches—first week.—Are swollen through infiltration of leucocytes, the surfaces raised and fawn-colored—the infiltration involves the submucous coat. The lesions are most numerous at the lower end of the ileum. Second week.—The surface becomes abraded; sloughs form which are often bile-stained. Third week.—Sloughs come away, leaving ulcerating surfaces. Typical typhoid ulcers are thus formed. A few solitary glands undergo the same process. At the end of the week the ulcers begin to granulate, but healing is usually slow. Mesenteric glands may undergo the same changes, but more often become swollen, red, and tender only, or break down into cheesy masses."

Note: In the *typhoid ulcer* (1) the main axis of the ulcer lies parallel with that of the intestine; (2) it lies opposite to the mesenteric attachment; (3) it has smooth floor and undermined edges; (4) it commonly leads to perforation.

2.

GLANDULAR HYPERTROPHIC ENDOMETRITIS.	GLANDULAR HYPERPLASTIC ENDOMETRITIS.	ADENOCARCINOMA.
1. Glands increased in size but not in number.	1. Glands increased in size and number.	1. Glands very greatly increased in size and number.
2. No proliferation of gland epithelium.	2. Proliferation of gland epithelium.	2. Very great proliferation of gland epithelium.
3. Gland structures nearly or quite typical in outline.	3. Gland structures more tortuous in outline.	3. Gland structures very atypical in outline.
4. Hypertrophied epithelium confined within the limits of the tunica propria.	4. Proliferation confined within the limits of the tunica propria.	4. The proliferating gland epithelium has broken through the tunica propria and is in direct contact with intergiandular connective tissue, and is multiplying in an atypical manner.
5. Gland tissue does not invade muscularis deeply.	5. Gland tissue does not invade muscularis very deeply.	5. Gland tissue may very deeply invade muscularis.
6. Can trace tortuous glands.	6. Can trace tortuous glands.	6. Glandular labyrinth; can not trace tortuous and atypical gland.
7. Stroma normal in quantity.	7. Stroma decreased in quantity, but clearly defined from glands.	7. Great rarefaction of stroma, so that glands touch one another. Glands have broken through basement membrane and invaded intraglandular spaces and muscularis.

(Dudley's *Gynecology.*)

3. Foci of infection may be primary and secondary. The primary foci are usually located in the skin or mucous surfaces or in tissues communicating with them. The secondary foci are the results of infection brought about by the agency of the blood or lymph.

4. *Appendicitis.* "In the mildest or catarrhal form there is merely retention of the contents of the appendix and slight disease (swelling and erosion) of the mucosa. The muscularis and serous coat may be congested and edematous, but are not extensively involved. The contents of the appendix are more or less mucopurulent in character. In the necrotic or gangrenous form the mucous membrane suffers rapid destruction and the muscular and serous coats are quickly invaded. Fibrinous peritonitis soon develops in the serous coat and over the adjacent intestines, either as a result of penetration of bacteria through the walls of the appendix, or in consequence of perforation of the walls. The local peritonitis serves the purpose of restraining the infective disease and prevents diffuse peritonitis. In cases of rapid gangrene, with early rupture or escape of abundant bacteria, general peritonitis may result before a restraining wall can be formed."—(Stengel's *Pathology.*)

5. A *tubercle* is a small nodule, found in the lungs, etc., in cases of tuberculosis, but also found in other diseased conditions. It consists of three layers, the outer one consisting of lymphoid cells, the middle one of epitheloid cells, and the inner one of giant cells. These layers are squeezed or compressed into a firm mass, which may caseate or undergo other pathological processes. There is no blood supplied to a tubercle. Its *origin* is due to the stimulating or irritating effects of the tubercle bacillus upon the fixed connective tissue elements, causing a round-cell proliferation. The *tissues most frequently invaded by it* are: Lungs, lymphatic glands, bones, joints, intestinal tract, peritoneum, skin, testicle, epididymis, brain, liver, kidneys, spleen, Fallopian tubes, ovaries, uterus.

(*To be continued.*)

THE DIAGNOSIS OF CHRONIC GALL-BLADDER PATHOLOGIES.*

BY ANTHONY BASSLER, M.D., F.A.C.P.,

NEW YORK.

PROFESSOR GASTROENTEROLOGY, FORDHAM MEDICAL COLLEGE, AND NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; CONSULTING GASTROENTEROLOGIST PEOPLES, BETH DAVID, CHRIST'S, POLYCLINIC HOSPITALS, ETC.

THE acute suppurative, gangrenous, or perforated conditions will not be described. These cases are comparatively easy to diagnose (although the actual pathology present is generally difficult to deliniate before operation), and since all require immediate surgical therapy, and this therapy is essentially the same in all, no description is entered into. This article pertains to the chronic cases in which there are no alarming acute symptoms, and which are the most numerous and the least often diagnosed.

In my gastrointestinal practice, pathology of the gall-bladder had been diagnosed in eight and one-half per cent. of one thousand consecutive cases. These comprise many types of histories and examination findings, and breaking from the old custom of classifying according to pathologies, I shall present a clinical grouping according to symptoms (subjective and objective).

In the grouping of symptoms making up more or less distinctive combinations which represent characteristic entities tending to the diagnoses of certain definite diseases we have the best means of diagnoses. The older clinicians were peculiarly apt in these, made so because in past days methods of laboratory procedure were meager and they had to depend upon clinical observations. This laboratory limitation made it that these men became most able clinicians, types of men that are strangely few in medicine now. The dependence upon laboratory, *x*-ray, multiple consultations, etc., is somewhat utilized as the method of to-day to make up the gap of thorough clinical training. The grounding of abilities in fundamental training is a long and expensive process, and few are the men who are willing to go through with the years that it takes. This is unfortunate because while apparatus to make diagnosis or assist in it is most helpful, the psychology of the human mind is not above being unwarrantably influenced by such methods, and the tendency is to become concluders from apparatus or laboratory results, and thereby automatic and removed from disease in the various presentations the same conditions are met with clinically. In no department of medicine is this so rife as in gastroenterology, in which the majority of men are more dependent upon the laboratory for diagnoses than clinical training, the latter sometimes being woefully lacking. This is especially unfortunate because in the vast array of diseases of the abdominal organs pretty much of the same individual symptoms are met with in them all. One reads in the literature "the colloquial symptoms of indigestion, gastric disturbance, indigestion," and such terms, which in their final analysis means that the author is indifferent, careless or deficient in knowledge of the symptomatology of abdominal conditions. Thus I have four criticisms—First, the placing of too much or entire dependence upon the laboratory for diagnosis; second, the employment solely of apparatus to make or exclude diagnoses; third, the deficiency of fundamental training in medicine when to diagnose abdominal conditions requires supertraining, and fourth, deficiency in analyzing symptoms and grouping them into symptom groups or complexes so they may be useful for diagnosis.

The first type of gall-bladder case is the one of years of history in which there have been remissions of slight symptoms. The complaint when the symptoms are on is comparatively simple. There is a run of distress in the epigastric region, accompanied with increased belching which may be between meals as well as after them. There is an uncomfortable feeling in the upper abdomen, the test meals showing a moderate increase in acidity in a unit of gastric filtrate. The patient is usually a female and most often one who has had children, although there is no close association between a childbirth and the symptoms. The biology in the bowels shows the presence of a saccharobutyric toxemia, the rectal mucosa a hypertrophic proctitis. The first heart sound is a little weak, although the systolic blood pressure may be elevated. There is some degree of tenderness on pressure on the gall-bladder, but this is not distinct, although the gall-bladder is the most sensitive to pressure of all of the organs in the abdomen. There may be tenderness along the lower intercostals on the right, and some increased tenderness on pressure on the right of the vertebræ from the eighth dorsal to the second lumbar. The *x*-ray shows nothing and the fluid aspirated from the duodenum is not distinctive. Some hyperesthetic nervous symptoms are present, and a little dieting, alkalies, bromides, etc., and the case remains away, generally to come back in a few months with a resumption of the symptoms complained of before. A strawberry gall-bladder is probably present.

*Read before the New York Polyclinic Medical Society December 1st, 1919, and the Medical Society of the County of New York March 29, 1920.

The next is the stout woman, usually of Semetic or Teutonic blood, who has been in this country for some years, in whom belching is most distressing, as well as postmeal hyperesthesia and perhaps an acidity that is above normal. She has slight chills for no apparent reason and points to the gall-bladder region as the seat of her distress. One is struck by the fact that whatever is the character or distribution of her subjective nervous complaints, her mind is definitely in her abdomen on which she puts her hand to locate the distress, and this is slightly to the right of the midline in the epigastrium and high up in the ribs. She tells you that the trouble came on after the birth of a child, or when you draw her attention to the connection she says "that's right." The saccharobutyric toxemia with hypertrophic proctitis is present as before, the tender intercostals and right spinal areas also. Chronic cholecystitis, perhaps adhesions, inspissated bile, commonly being the cause.

The next case resembles the first two excepting attacks of biliary colic have been present with the history, or presence of jaundice in about a third of them. One will tell you that heat, rest, time, and low diet, or abstinence from foods for a few hours are all that is necessary to control the attacks, whereas the next one will require morphine to accomplish it. What is interesting now is that gastric hyperacidity does not exist, but more times a normal acid content, or perhaps below normal, or an achylia. The gall-bladder here is very tender and direct pressure upon it elicits distinct pain. Not uncommonly the liver is somewhat enlarged, particularly the left lobe. The majority of these are in women, especially those who have borne children, but they also occur in men.

Such cases in men, however, while they may be stout, are usually in those of the thin type. My experience with men is that the symptoms are rather more definitely centered in the gall-bladder region than in women, the history and degree of epigastric distress more definite, the remissions less marked—the latter excepts the attacks of biliary coli, which come and go in both the same. All of them are instances of cholelithiasis, and cholecystitis is always present when gallstones are.

One now has to add the case in which the symptomatology points to gall-bladder disturbances, but in which there is an added symptomatology of pyloric obstruction, due to band formation or thickened tissue. This type of man and woman is thin, the history is very chronic and insistent, the age about fifty and the pathology present is usually that of hydrops or markedly contracted and thickened gall-bladder with stones.

Also, more rare than those described, is the one presenting the mentioned symptoms and types, but who had had an attack of infectious disease, usually typhoid fever, in which the symptoms follow four or more years afterward. Usually they are Americans, rarely Jewish or Europeans, and they may be rather young, perhaps in the thirties, while most of the gallstone cases occur in those over forty. These occur as frequently in men as in women, although in the non-infectious cases women make up three-quarters of those seen. Another type of individual is a man presenting symptoms above described, in whom they began after about two years of sedentary life, he generally having been active physically for years before this. From walking to buggy was comparatively safe enough, but from walking to automobile and hired chauffeur has caused the formation of many gallstones that are causing trouble. One sees this more conspicuously in physicians than in any other group of people, although those that got rich quickly made up the bulk. In this connection I would mention that in obstinate urticaria think of gallstones as a possible fact, not because gallstones cause urticaria, but because it is caused by high degrees of saccharobutyric toxemia, and this, in my opinion, is the commonest cause of cholelithiasis.

Of interest now is the distinctly masked case as far as presenting subjective or objective gall-bladder symptoms are concerned, in which, after careful laboratory work, a diagnosis of chronic pancreatitis is warranted. Such not frequently are chronically diseased gall-bladder cases in which the disturbances of pancreatic function is due to thickening of the head of the gland, this being secondary to disease of the gall-bladder.

The case presenting an attack of biliary colic in which the stone is engaged in the cystic or common duct, producing pain, is well known to you and easy to diagnose. The type and radiations of the pain, perhaps rigor, slight elevation of temperature, the vomiting, nausea, profuse sweating, depression of the circulation, etc., are all as characteristic as is the relief of pain from morphia.

I now will remind you that about a fourth of all people over 60 years of age have gallstones, and thus it is that a large number of people are carrying diseased gall-bladders around without knowing it. Regarding these I am inclined to agree with Mayo that there are no innocent gallstones. It is true that many of these people have no symptoms referring to the gall-bladder, and from that standpoint they may be judged as innocent, but if you keep the possibility of their presence in mind and study states of illness or disturbances in the general state of health, one often will see cases in which you come to the conclusion that pathology in the gall-bladder may be causative, however remote or masked the conditions may be. As my experience multiplies, more and more of such old people are seen and one can do little for them in substantial ways unless the gall-bladder receives attention.

Feeling best when no food is in the stomach; most distress one to three hours after meals; headaches, vomiting of bile-stained mucus on arising mornings; increase of symptoms at menstrual times; trembling sensation in stomach regions, and loss of weight are present in cases but not characteristic enough to be diagnostic, and need only be mentioned. As you know, they are present in other abdomnial conditions than disease of the gall-bladder.

My opinion on the three indirect means of examination, namely, the *x*-ray, duodenal tube, and hypercholestermia leaves much to be said. To be brief, however, the following may be given as my opinion:

The *x*-ray is both useful and a fallacy. Among the best *x*-ray men attestations of percentages range all the way from 33 to 95 per cent. When two men, each equally good, state such extremes, and there are many with percentages between, con-

clusions are required for understanding. I do not believe that differences in technique and interpretation can account for such disparities, because these are about the same in all who do good *x*-ray work. I have obtained definite shadows in 96 out of 300 cases in which I believed gallstones to exist (32 per cent.) and I cannot do better than this. Almost weekly I am required to judge a case in which an *x*-ray diagnosis of gallstones had been made, there being practically nothing else to base this on. From the experience with these I have come to the conclusion that no one is warranted to state that gallstones are present from an *x*-ray examination alone, and present such in literature, from the platform or in discussion, unless in each instance they had been proven by operation, and unfortunately this is not the rule with the men who have presented the high percentages. When a means of examination gives me 68 per cent. of negative findings in cases proven by operation, I cannot feel other than with the technique to-day that this means of diagnosis has only moderate value. More may be said in its favor in diagnosing chronic cholecystitis with large gall-bladder containing inspissated bile. *X*-ray examination should be engaged in to make diagnoses of cholelithiasis and cholecystitis, but in the case with a distinct symptomatology it should be explained to the patient in advance that if the *x*-ray examination is not conclusive, the diagnosis stands anyway.

Aspiration of bile from the duodenum with the duodenal tube, and noting its presence, character or its absence (bile duct obstruction) is even less useful in a general way than *x*-ray examination. Some of the most perfect examples of normal returns I have seen have come from cases in which operation proved the presence of markedly diseased gall-bladders, gallstones and even obstruction, and as far as the average gallstone case is concerned, it is quite valueless. Work is being done in this connection which may enhance the practical value of this means, but up to the present little more about it can or should be said.

The examination of the blood for cholesterin has been employed as a means of diagnosis. This is rather a far-removed means and so high is the percentage of gallstone cases that have not got an increase of cholesterin in the blood that as a means of diagnosis it is not dependable, although as a means to suggest proper dietetic and hygienic therapy it is often enough of value.

The diagnosis of gall-bladder pathologies is not difficult. Naturally the less the pathology the fewer and less distinctive the symptoms, the more the difficulty, and the greater the proportion of cases that are missed. In it all, however, the clinical history and the objective and subjective symptoms are of the most value and the indirect means distinctly less so, although they should not be neglected because occasionally they will give a finding that will be most helpful. What perhaps is the most useful of all is the development of that so-called "sixth sense" that comes from ample experience and close study of the clinical aspects of the cases in which each case, if carefully studied, does more eventually toward diagnostic acumen than any other means I know of.

21 West Seventy-fourth Street.

SURGERY OF THE GALL-BLADDER.*

By JOHN F. ERDMANN, M.D., F.A.C.S.,

NEW YORK.

THE history of gall-bladder disease is filled with involvements of other viscera and with degenerative changes in the viscus itself that have been proven amenable to surgery. While we see only failure of cure, or protracted illness, in the medical treatment, and then comparing the cures and preventions of degeneration with collateral associated viscera with surgery, one fails to see the efficiency of continuing medication.

Therefore, surgery is the advised treatment for indigestion due to gall-bladder disease without colic, for acute inflammatory changes, for repeated colic attacks, and for evidence of obstruction in the hepatic system, be it due to calculus or adventitious growth or exudate; for strawberry gall-bladder, for empyema of the gall-bladder or inflammation (cholangitis) of the biliary system; for adhesions, for gangrene, or malignancy; for hour-glass contractions, for hydrops of the gall-bladder, and also for atrophy of the same. Finally, for the prevention of malignancy, the incidence of which I have recently reported as about 7 per cent. in all patients suffering from gall-bladder symptoms.

In addition to preventing malignancy due to calculi, etc., by irritation, we obviate morphinism, by operation in those patients in whom one sees repeated colics, with no post-colic inflammations, but in whom the dose of morphine rapidly increases with the rapidly recurring attacks of colic. One of the most pitiful patients I have had is a young married woman who, at the last time I saw her, was taking 16 to 18 grains of morphine per day, and had become so addicted to morphine as to refuse surgical interference, fearing the cutting down of her daily supply.

Loss of weight: I have frequently remarked to my classes that the loss of weight is greater in some gall-stone cases than in the malignancies of other viscera. This great loss I am unable to explain, as many of these patients have neither palpable nor visible involvement of the pancreas, and the majority have no involvement of the common duct.

Spontaneous perforations and later deaths from peritonitis, or a secondary fistula into some adjoining viscus, or the formation of a sub-phrenic abscess or a perforation into the pleural cavity, with a thoracic empyema opening, discharging biliary calculi and bile—all have been seen by me and all could have been avoided by properly timed surgical intervention.

It is our failures in life that benefit us most. They make us think more and advance or curtail our technique and treatment; while the successes are readily forgotten, or looked upon as only the expected. Failures in gall-bladder surgery, including, of course, the surgery of the duct, are chiefly due to overlooked stones—hepatic calculi that later come down; the occasional, and fortunately rare, but not rare enough, injuries to the duct or ducts; reformation of stones, empyema, especially where an ostomy has been done; and finally, the mortality or mortalities. When we recall that today the mor-

*Read before the Medical Society of the County of New York, March 29, 1920.

tality of gall-bladder surgery is under 4 per cent. and even as low as ½ to 3 per cent. in the hands of our hospital clinicians, we can present an argument to our patients that shows a percentage in their favor, when compared to the outlook in a mortality sense from medical treatment; while presented from the angle of efficiency and morbidity, surgery will far outweigh the medical consideration.

Success in this field depends upon more than the one factor—the gall-bladder—as often there are associated lesions that must receive definite attention at the same time. Of these, there is the occasional duodenal or gastric ulcer; the usual chronic appendix, or the occasional acute to gangrenous one, accompanying the acute gall-bladder; the intercurrent or concurrent pancreatitis—from acute hemorhagic through all phases of the chronics, etc., etc.; fistulous communications between the gall-bladder and adjoining viscera, quite a few of which have been corrected in my work.

The operative consideration of a diseased gall-bladder or an involved biliary system brings up the ever pregnant question: Shall an ectomy or an ostomy be done? I am in favor of doing a cholecystostomy only in those patients who present such a degree of physical and constitutional involvement as to hazard their lives by a few minutes longer anaesthesia and the loss of a few drops more of blood, but I must state that I do not believe that I have been compelled to do one ostomy, in the past two and one-half years, out of almost 300 operations upon the gall-bladder for the above reasons.

Also I do a cholecystostomy in a few patients per year, possibly two or three, when the pancreas is involved, as I feel that doing a choledochostomy would present a greater hazard than doing a preliminary cholecystostomy, and later ablating the gall-bladder and opening the duct. When a malignancy exists in the pancreas, or is suspected, I am in the habit of performing a cholecysto-gastrostomy or a cholecysto-duodenostomy, etc., and not, as some operators advocate, a permanent cholecystostomy, as in the latter operation, the bile salts, etc., are lost to a great degree, while in the former all are saved by drainage into the anastamosed viscus. This type of operation also forms an anatomical spillway for the pancreatic juice when the obstruction is at or near the papilla of Vater.

Cholecystectomy is the ideal operation for cure and efficiency as compared to cholecystostomy. In the latter operation we are likely to have adhesions, recurring stones—*i.e.* reformed, overlooked stones—recurring empyema, etc., in over 4 per cent. of all so operated, and a prolonged drainage, as compared with that of the ectomy.

The foregoing summarizes the inefficiency due to morbidity. Efficiency is what finally counts as the cure in these days of strife and success.

Granted that cholecystectomy is a more difficult operation and attended with, therefore, more danger to the patient, nevertheless, in the hands of the hospital clinicians, strange to report, the mortality is in fact below that of cholecystostomy. This I showed some four years ago, in a paper reporting over 300 operations of my own. The bed-ridden time in cholecystectomy is usually 10 to 15 days; in cholecystostomy 15 to 20 days, with a draining wound for some time after.

Cholecystectomy removes a diseased structure; cholecystostomy leaves a diseased one for future trouble.

I no not believe today the argument advanced some years ago, that the absence of the gall-bladder is a factor in the production of pancreatitis. All the patients whom I have operated upon for pancreatitis, acute, hemorrhagic, etc., had their gall-bladders in them when I made my first incision, but the majority of them not after—unless I used the gall-bladder as a means of drainage.

Some of the failures in ectomy are due to insufficient removal, as seen occasionally where an operator has made a partial removal, fearing to approach the cystic duct. Another failure is the fortunately rare but not rare enough injury to either the common or hepatic ducts, which creates havoc with all connected with the patient. As to the so-stated postoperative frequent dilated cystic duct, which is said to give origin to secondary trouble, both Deaver and myself have seen very few instances, and are inclined to believe in its rarity.

The operation of ectomy may be done from below upwards, or in the reverse way, it matters not which; but I am quite sure that a few operations done from below upward will convert the operator from the above downward method. In the acutely inflamed, high-placed gall-bladders, I am very much attached to the sub-serus operation of ectomy, stripping out the mucosa and muscularis—down to the cystic duct.

In the presence of jaundice I do not hesitate to operate if the jaundice is of the acute variety—that is, when it exists but for a few days. When the jaundice exists over a week I demand a series of coagulation tests and transfusion when necessary. In fact, a coagulation test is the safe procedure in all jaundiced patients. Transfusion after operation with oozing is of little avail, while bringing the coagulation time down to safety before operation by preliminary transfusion, will prove successful in the majority of instances.

Persistent or deepening jaundice is not always a sign of malignancy, as frequently an impacted common-duct stone presents just such a condition, but the majority of these patients present a malignancy in some point of the biliary outlet.

Mortality.—The deaths from operations in gall-bladder and the biliary system can rarely be attributed to peritonitis, but frequently to nephritis or pneumonia. It is rare that the biliary patient has no albumen or casts in his or her urine. It is frequent enough that the biliary patient has a degenerated heart muscle, due to his biliary condition, as proved by the repair after successful operation. The pneumonias may be attributed to at least two sources: a cardiac involvement before operation, and respiratory restraint as a direct result of the operation.

Among the difficult questions that arise when the gall-bladder patient consults the surgeon is that of pregnancy with a definite attack or attacks of gall-bladder involvement. Only recently a patient five months pregnant with weekly explosions of grave attacks of gall-bladder pain and ½ grain morphine injections, expressed the statement: "If I risk losing my baby by operation, I would rather risk being cured for morphinism." I could but tell

her to go on, and in case of an acute—meaning inflammatory attack to send for me.

Let me summarize with but one argument. In view of the frequency of malignancies of the gall-bladder and the lower mortality by operations than the frequency of malignancy, then by all means—*when* a diagnosis of cholecystitis is made, advocate the lesser evil—"Operation!"

60 West Fifty-second Street.

THE DIAGNOSIS OF SPINAL CORD TUMORS.*

By HYMAN CLIMENKO, M.D.,
NEW YORK.
ADJUNCT NEUROLOGIST TO MT. SINAI HOSPITAL AND THE MONTEFIORE HOME.

In 1888 Sir Victor Horsley[1] showed that spinal cord tumors can be removed with good results. Ever since neurologists have endeavored to establish criteria by which an early diagnosis of spinal cord tumors may be made. As yet such a diagnosis is more of an art than a science. We are still far from being able to tell, with certainty, whether in a given case we are dealing with a neoplasm, a systemic disease, or a multiple lesion of an infectious character. At first this seems paradoxical. The anatomy and functions of the spinal cord are perhaps better known than those of any other part of the cerebrospinal axis. It would seem that any focal lesion produced by pressure should be recognized at once. When, however, we consider the consistency of the cord, its complexity of structure and multiplicity of function, the difficulties in establishing such a diagnosis are at once understood.

The spinal cord measures through its largest transverse diameter, the cervical enlargement, 15 mm. (Obersteiner). Through the periphery of either half pass at least eight well-defined tracts carrying important motor and sensory functions. Its central grey presents important trophic as well as sensory motor functions. If we now remember that the consistency of the cord in life is that of soft putty, it will be easy to conceive how any small pressure upon it is liable to disturb the function of the entire structure and to give a multiplicity of symptoms which are difficult of interpretation. This is particularly true when the diagnosis is to be made with reference to the transverse diameter of the cord. Fortunately the more important, the vertical localization, is comparatively easy, for here we are guided by so-called level lesions which are recognized mainly by sensory changes and are due to root distribution.

For all practical purposes we are called upon to establish a differential diagnosis between an extramedullary and an intramedullary tumor. Bruns[2] is right when he says that it is difficult or impossible to differentiate between extradural and intradural tumors. Nor is such a diagnosis needed for practical purposes. In this paper we will not enumerate the oft repeated and socalled classical symptoms, but, after giving the histories of some cases of spinal cord tumors that occurred in the service of Dr. Abrahamson of the Montefiore Hospital, will try to give the reasons that led us to believe that the diagnosis was neoplasm of the spinal cord.

Case I.—H. R., 38 years old, widower, salesman, born in the United States, entered Montefiore Hospital November 24, 1913; discharged, cured, on July 1, 1914. Father dead at 76. Cause senility. Mother dead at 60. Cause senility. One sister died of tuberculosis at 20 years. Four brothers died in childhood, cause unknown. One elder sister had a temporary puerperal insanity. Otherwise family history is negative as to any nervous ailment. Patient went to school until 14 years of age, went to college for two years, and since then worked for various commercial houses, always in a capacity which required mental rather than physical labor. Patient did considerable walking; was an athlete—a runner. He ate and slept well and regularly. Bowels regular. Urination normal. No nocturnal urination. Gonorrhea four times, last time at 31 years. Denies knowledge of chancre. While wife was living had intercourse at least once a night over a long period. Had diphtheria at 4 years; good recovery. Grippe at 15 years. Removal of lipoma on shoulder some years ago.

Present History.—Gradual onset three years ago with burning-like sensation in right foot. One month following this began to notice numbness in right calf. No pain. Numbness traveled upward to upper portion of thigh. Formication over affected limb. Now began to notice weakness in this limb. About six months later began to notice weakness and twitching of left lower limb. No paresthesias or pain. Right limb was weaker than the left until one and a half years ago when the left was suddenly almost completely paralyzed. Soon after this the right was similarly affected. After this, managed to walk with aid of crutches. Hands never affected. One year and seven months ago, noticed girdle sensations at level of umbilicus, which are still present. Was never incontinent. Increased frequency of micturition. Act of micturition very slow. Very constipated. Weakness of lower limbs increased steadily, and was admitted to a hospital just barely able to walk. Here was operated on for spinal cord tumor, but apparently nothing was found at operation. Since that time of operation has been chair- or bed-ridden. Before operation had distinct areas of anesthesia and thermal anesthesia. Since operation claims latter has disappeared, but no improvement in motor power. Stiffness has increased remarkably. Never had bedsores. Has had twitching of muscles of lower limbs and frequently sudden contractions. No convulsions or fainting attacks.

Chief Complaints.—Inability to walk. Girdle sensations. Spasticity. Occasional diplopia and blurring of vision.

Additional Notes.—November 20, 1913, for first time lost his urine while trying to hold back from urinating. About seven years ago he noticed, when dealing cards, an extensor cramp of little finger of left hand. Right hand similarly affected. Disappeared about a year later. About five years ago, he experienced shooting pains about the second dorsal vertebra, shooting around into the chest anteriorly, following the distribution of the second dorsal nerve. This pain was spasmodic in character.

Physical Examination.—Adult, male, well nourished, lies flat on back, cannot sit up by himself. Stands with support. Cannot walk. Scar at about middle of dorsal spine. Cranial nerves are all negative. Muscles of neck as well as those of the upper extremities are negative. Spine held rigid, distinct tenderness both to pressure and percussion at the second, third, fourth and fifth dorsal spines. The lower extremities are spastic, limited in motion, toes cannot be moved. Skin over both feet dry and scaling. Double Babinski, double ankle-clonus. On November 27, a complete sensory examination was made (See Chart). Distinct hyperalgesia, best elicited with a needle, and extending over the area of the second, third, and fourth dorsal roots. At the fifth and sixth there is a distinct belt of heat algesia. From a level drawn between rims of the crests of the ilia there is thermal anesthesia, but this is not constant. At times slight perception of temperature is present. From middle of leg downward the thermal anesthesia begins to be more constant. On level of the second to the fifth dorsal, both sides, a zone of hyperaesthesia about 7 inches in width. At seventh and eighth dorsal, similar zone of hyperesthesia, as likewise at upper lumbar. From upper edge of os innominatum downward on left side there is analgesia mixed with areas of hypo- and hyperalgesia. On right side, an

*Read before the Eastern Medical Society, New York, March, 1920.

area of hyperaesthesia just at gluteal fold. *Touch:* Absent along left hip posteriorly, and absent in spots along dorsal surfaces of left leg. Anteriorly: Hypalgesia at level of eighth rib on left side. Hypalgesia for about one-half inch at seventh rib, then a hyperalgesia for about the same distance. Another area of hyperalgesia about two inches above umbilicus. At two inches above Poupart's ligament there is another area of hyperalgesia, likewise in groin, likewise in upper third of right thigh. Analgesic band for three inches at upper part of left thigh. On legs of both sides hyperalgesia and hypoalgesia alternate without any analgesia. From upper part of thighs downward there is a disturbance of temperature.

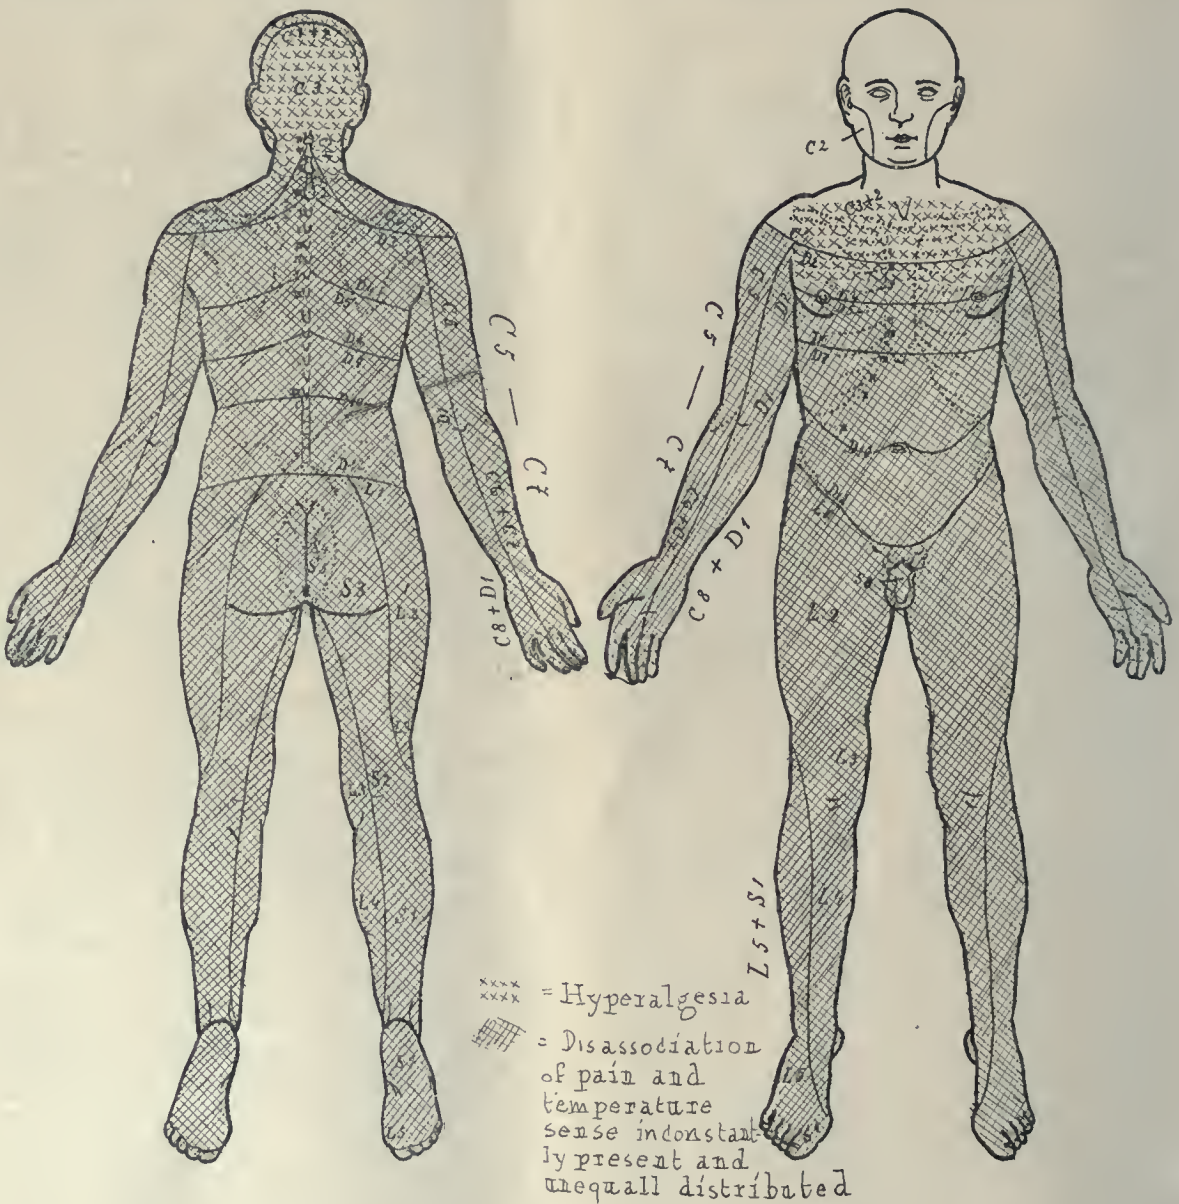

FIG. 1

Wassermann both in the blood and in the cerebrospinal fluid was negative. Urine negative.

Operation.—On January 2, 1914, diagnosis having been established, operation was performed by Dr. Elsberg. The usual exposure of cord made by median incision, stripping back musculature, removing spinous processes and laminæ. The cord opposite the fourth and fifth dorsal first exposed. Dura incised. Very little fluid escaped. No pulsation of cord. Vessels of cord congested. Probe felt obstruction about one inch above upper angle of exposure. The second and third dorsal spines and laminæ therefore removed and dura split upward. A localized extramedullary tumor (about 3 cm. long and 1½ cm. wide) lay on left side of cord, compressing the latter and pushing it to the right. The tumor was readily shelled out, without oozing and without damaging nerve structures. It lay opposite the second and third dorsals. After removal of tumor there was an escape of considerable cerebrospinal fluid and the cord appeared to begin to fill in the gap.

Postoperative Notes.—On January 6, 1914, movements of the the feet and toes are still conjoined. Legs are spastic. Deep muscle sensation and pain are present. Localization sense fair in left leg.

On February 24, 1914, the patient states that the girdle sensation, which was formerly like a wide band at level of umbilicus, has now moved down and is at level of Poupart's ligament; it is like a string, and less in intensity. Urination is much improved as to force of stream, and he feels inclined to urinate when necessary. *Reflexes:* Knee jerks both exaggerated. Double Babinski, double clonus. Double Oppenheim, Mandel and Gordon. Patella jerk not obtainable. Cremasterics not obtainable. Abdominals present except both lowers. Can raise both feet well off the bed. Moves toes. Can flex and adduct, extend and abduct legs. To adduct, a sudden sharp effort must be made. No ataxia of legs. Two-point localization is not normal in both legs. Pain in thighs. *Deep muscle sense:* Knows position of big toes, but occasionally says they are down when up.

Rarely calls up, down. Patient is potent; now has erections such as he did not have for two or three years before operation. Has been complaining lately of sharp pain in occipital region, worse at two or three o'clock in the morning, which keeps him from sleeping.

March 30, 1914; for past week has been able to stand alone for a few seconds, entirely unsupported, and to walk around the ward very slowly when supported by a cane, and to support himself with other hand on chair. There is still marked spasticity but not nearly as marked as before. Patient claims he is regaining strength in his legs. Twitchings of legs are very much less than before, only occasionally when in bed. Twitchings of muscles are worse in damp weather. Still marked ankle clonus in both legs. Achilles jerks equal in both legs. Patient is getting hot baths and is noticing a marked relaxation and improvement right after the bath.

April 22, 1914; patient claims that for past two weeks he has been experiencing more rigidity in his legs. However, the rigidity is not so bad as two months ago. Girdle sensation is lower than it was, about four inches below the umbilicus. Knee jerks both exaggerated. Double inexhaustible ankle clonus. Abdominals, all present. Cremasteric, present on right side. Double Babinski, Oppenheim, Mendel and Gordon. Can raise both legs together and separately off the bed. Can adduct, abduct, flex and extend both legs. Deep muscle sense mistaken at times, but when same is repeated he gets it correctly. Tactile and pain sense apparently normal all over. The level of hyperaesthesia and hyperalgesia previously recorded has entirely disappeared. *Temperature:* There is dissociation on surface of left thigh, distinguishing cold, but also calling hot tube cold. This reaction is obtained over outer side of right leg. There is also delayed sensation to temperature over the same areas. At the level of the umbilicus there is delayed sensation to heat, particularly over the right side.

May 18, 1914; patient's general condition is much improved. His spasticity is less. He is able to walk with the aid of two canes.

To sum up: The patient manifested subjective sensory symptoms consisting mainly of parasthesia. These were followed by motor irritative phenomena, which in turn developed into a paraplegia of the Brown-Sequardian type, accompanied by a girdle sensation apparently at the seat of the lesion. A level was established in a reputable hospital and the patient while there was in the service of a leading neurologist. We will presume that the level at that time was correct. Due to the peculiar situation of the tumor no real or rather correct sensory root symptoms could at the time be estab-

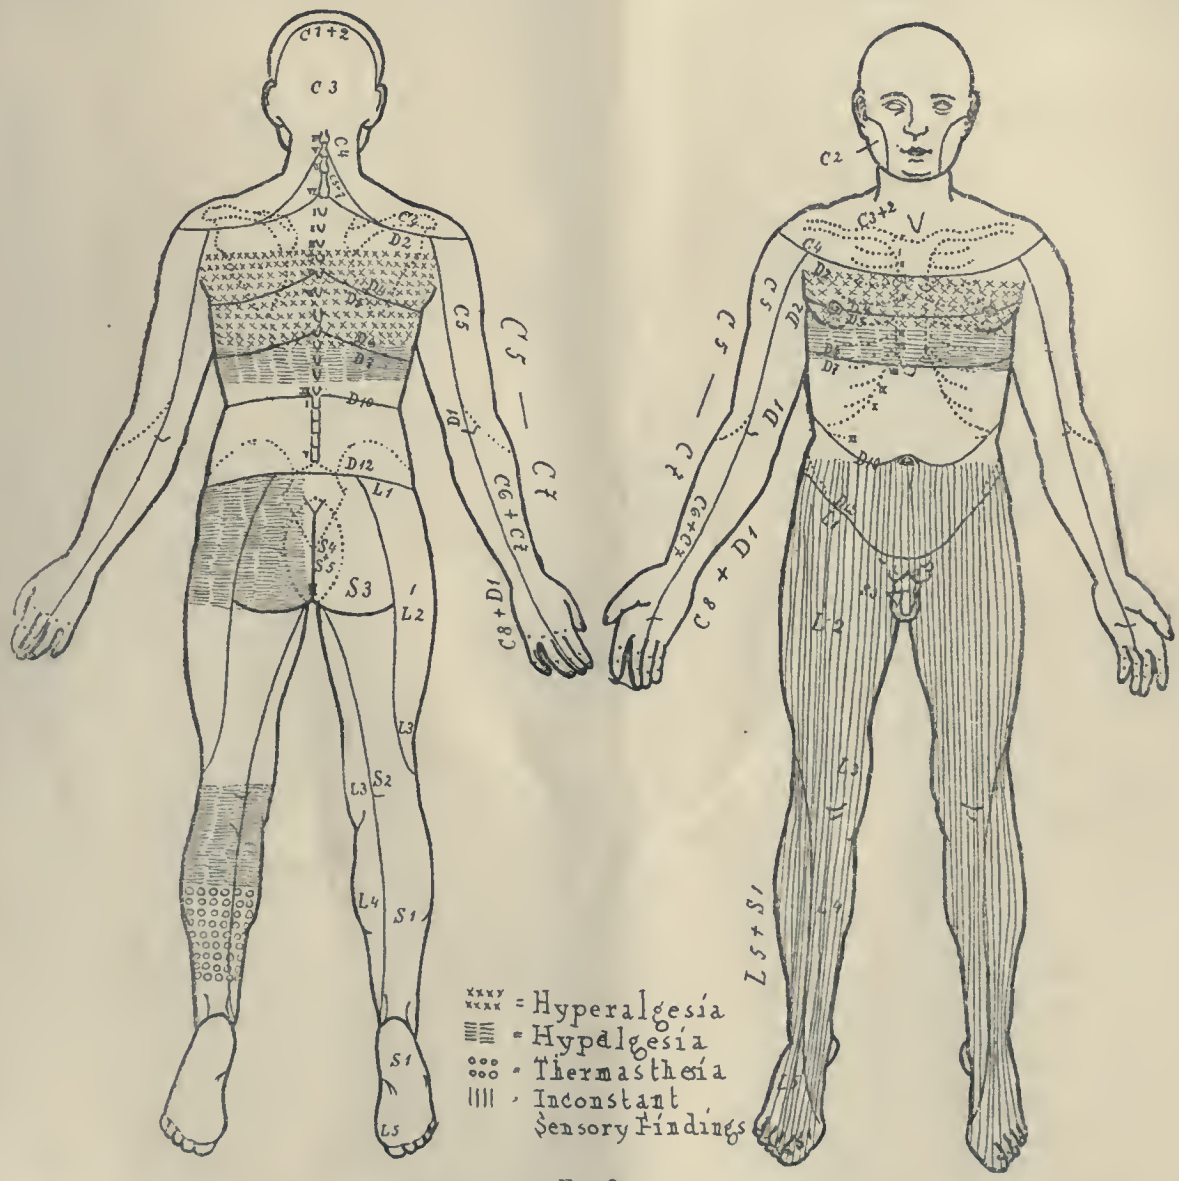

FIG. 2

lished. Only later, when the tumor grew larger and pressed upon or irritated the dorsal roots could a correct level be made out. The usual mistake of putting the level too low was made. It is probably safe to assume that the wrong level was established not according to root symptoms, but rather due to symptoms resulting from tract changes which had already taken place at the time of the first operation. In this case for all practical purposes the level moved upward, thus upsetting the classical dictum that when the level moves upwards the tumor is probably intramedullary.

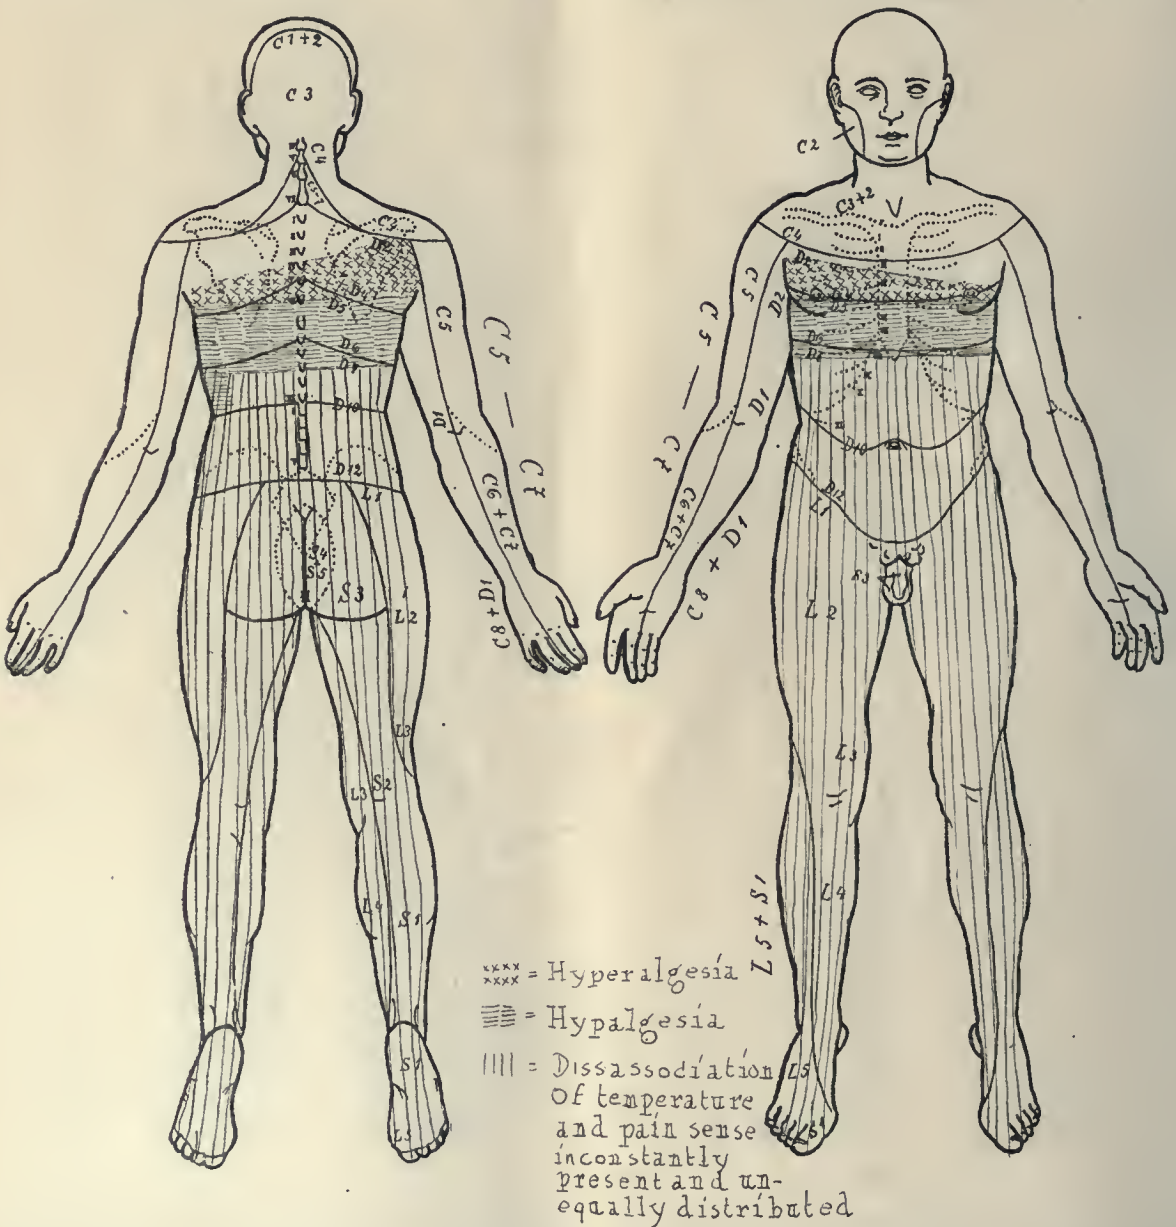

FIG. 3

CASE II.—C. W. Age 45 years. Austrian, widow. Admitted August 21, 1919—still in hospital. Family history and previous medical and surgical history, negative. Habits normal. Menstrual history normal; still menstruates; periods same as before, except that they last two days instead of seven. Married at fifteen. Had nine children, six alive and well. No miscarriages. Venereal history negative. Present illness began suddenly one year before admission with pain in the right chest posteriorly. She went to various clinics, where she was given liniments, but her condition was not improved. On admission, the patient stated that she has severe pains in the epigastric region in addition to the other pain in her chest. She often has the desire to cough, but cannot because of the pain. There were never any other symptoms present.

Summary of Complaints.—Inability to walk. Pain in posterior part of right chest. Epigastric pain. Left bladder disturbances.

Physical Examination: Patient is a middle-aged woman; fair nutrition; expression of pain in face; all the cranial nerves are negative. Teeth are absent; pharynx congested. Movements of head are normal; thyroid not palpable. Slight lagging of chest during inspiration. Heart somewhat enlarged to the right. Liver and spleen are not palpable. Lungs are negative. Few glands are palpable in right axilla. Patient is able to stand, gait is spastic and steps are short, with a good deal of ataxia. Double Babinski; double ankle clonus; both knee jerks are lively. Right crossed abductor reflex arc present. Patellar reflex is present, but no patellar clonus. Active movements in both lower extremities are limited but there is no complete paralysis. Beginning at about the dorsal vertebra on the right side, down to about the fourth, and beginning at about the fourth dorsal vertebra on the left side, there is a line of hyperalgesia. From about the sixth, seventh and eighth dorsal vertebræ there is a line of anesthesia on the right side. On the left side the line is not distinct. There are

sensory disturbances below that level. All the abdominal reflexes are absent. Bladder incontinence. Following lumbar puncture, *a typical Brown-Séquardian syndrome developed.*

Laboratory Findings: Wassermann of the cerebrospinal fluid showed three plus, five cells, and globulin two plus. The cerebrospinal fluid showed a distinct xanthochromia with massive coagulation.

Operation.—October 1, 1919. Laminectomy Dorsal V-VI-VII. Typical removal of arches. Considerable venous oozing, easily controlled by packing. Dura incised; tumor seen at upper end of dorsal incision; therefore, removed the fourth dorsal. Incision of dura, tumor about three inches long and one and one-half inches wide; partly cystic. Entirely on right side of cord between dentate ligament and fifth root. Fifth root divided as in diagram. Tumor shelled out. Practically no bleeding.

January 28, 1920; patient up and about. Walking, but with support. Complains of occasional shooting pains across the right side of the chest.

CASE III.—F. G. Female, single. Cigarette packer. Age 20. Admitted April 18, 1919. Family history negative. *Past personal history:* Occupation, clerical worker for four years. Worked under good hygienic surroundings. Habits: Sleeping and eating regular. Tea and coffee to moderate excess before onset of present illness; no alcohol; no drugs or medicine. Weight 112 pounds one year ago. *Previous illnesses:* Acute infections, none. Paralyzed at ten years of age. In bed for four weeks unconscious. No trouble after that. A definite history as to what this was cannot be obtained. Operations and injuries, none. Headaches, none. Eyes negative up to present illness. Ears, nose, throat and teeth negative. No history of any cough or night sweats. Cardiac and renal history negative. Constipated since onset of present illness. Menstruation began at fifteen. At first, period lasted seven days, now only five. Intervals very irregular, sometimes five weeks and sometimes as much as seven weeks. No insomnia or convulsions.

Present Illness: In June, 1918, patient complained of floating black spots before the eyes. She saw double for about four days. Glasses corrected this and she has never had this disturbance since. In July, 1918, on waking up one morning, patient noticed that her hand (left) felt heavy. She could move it around but only with difficulty. There was present at this time sharp pains in the back of the neck on the left side. The pain radiated down the left arm and up the back of the head. At the end of two weeks she noticed that she could hardly use her left hand at all and that both of her legs felt weak and heavy, the left much more so than the right. The pain, drawing and sharp in character, went down through all the extremities. She could walk all right but would drag her left foot, which was extremely weak. In September, 1918, she was admitted to the Mt. Sinai Hospital where she remained for three weeks. While in the hospital, she says that she had some sensory disturbances on the left side of the body. In February, 1919, patient received a burn on left shoulder while standing up against a radiator. She did not know she was being burnt until one day afterward when she noticed a blister over the left shoulder. She has never had a similar burn since then. Ever since the onset she has noticed muscular twitchings which go down her left arm. She has also noticed that the fingers of her left hand have a tendency to bleed on slight provocation. In the past few months she has also noticed that her right arm became weak and heavy. For the past six weeks she has been unable to walk at all, due to increased weakness and heaviness in the right lower extremity. The sharp, drawing pains have been continually present. She has never had any disturbances in micturition or defecation. History of continued hiccoughs some time last January. Lasted for several weeks then disappeared.

At the present time she complains of inability to walk, duration six weeks; paralysis of left arm, duration ten months; paralysis of left leg, duration nine months; paralysis and coldness of right leg, duration nine months; weakness in right arm, duration four months; sharp drawing pains radiating from neck to all lower extremities, duration ten months; diminished sensation in left arm.

Status: Young girl, emaciated, unable to stand or walk. Patient in a recumbent posture. Marked lateral nystagmus to the right; right side of face is flattened. No lymphatic enlargements. Third and fourth cervical vertebræ are prominent and tender to percussion. Heart and lungs negative. Abdomen rigid, which makes examination difficult. Tendency toward pes cavus on both sides. Apparent atrophy of musculature in both legs. Muscles of both upper extremities are wasted with the exception of the deltoids which are well preserved. Marked atrophy of intrinsic muscles of hand. Marked atrophy of skin of all the toes. Movements of toes and ankles fairly well performed. Rotation of feet is well preserved. Lifts upper right extremity, *in toto*, to about two feet from bed, while the left is lifted only about six inches. Distinct left Babinski. Right Babinski is difficult to obtain. Left ankle clonus. Right exhaustible clonus. Passive flexion of both knees is not painful, but passive extension is very painful at the right knee. Anesthesia of the outer surface of the right leg and also of the interior surface of the right thigh. On the left side there are unequal distributions of anesthetic areas, but far less in degree than on the right side. All the active movements in the left upper extremity are absent, and diminished in the right extremity. Passive flexion of head is painful. For all sensory disturbances (See Chart). The paralysis is of the flaccid type in the upper extremities. There is a dissociation of temperature sense, for which see chart. Electrical reactions give D. R. in the intrinsic muscles of the left arm. Right pupil is larger than the left. There is also marked wasting of the chest muscles as well as the pectorals. Paradoxical incontinence.

On January 15, 1920, operation. The third, fourth and fifth cervical vertebræ were opened. Cervical cord much swollen, evidently diffuse intermedullary growth.

All the laboratory tests were negative. Xanthochromia absent.

Analyzing these three cases, we see that pain is a common factor in all of them. It expressed itself differently, however, in each of these cases. In the first two the extramedullary tumors, it was an early symptom. In the third, the intramedullary tumor, it was of later development. In the first case the pain was more like the type of paresthesia at the beginning, and only later did it assume the sharp, lancinating character. In the other two it began as a severe sharp, cutting pain, and continued all through the course of the disease. This subjective symptom, pain, is a very valuable guide when properly interpreted. In eliciting this symptom the patient's psyche must be taken into consideration. It is only the intelligent and level-headed patient who will describe intelligently and accurately the seat of the pain, its character, and radiation. The emotional and restless individual with his bizarre, exaggerated statements often misleads the examiner. "Weh" covers everything with the Jew. The negro has his pet-word in "misery," and the Italian adds a toss of the head to "dolore." Only through persistent additional questioning can the character of the pain, at times, be established.

Another danger with these people is that they are often unconsciously led into answers. Perhaps the best way is to watch the patient's facial expression when the right question is put and the proper answer is given. The facial expression is particularly valuable in testing for tenderness. Pain as a diagnostic factor becomes still more valuable when it radiates along a root distribution. In our first case pain, in the beginning, was a negligible factor. In the second and third it assumed the character of root pain. We must state, therefore, that pain, while present in many cases, is not an essential symptom in the early diagnosis. If,

instead of the word pain, we would say that one of the first symptoms is a subjective sensory disturbance, we would be nearer the truth. Subsequently, however, pain became an essential factor in all the three cases. It is important to point out that in all of these cases the pain traveled along the distribution of a root. This is an essential feature, for no matter where the tumor begins it subsequently attacks the spinal root and more frequently the dorsal roots. In our first case it expressed itself as a constriction around the chest, in the second as a girdle sensation, and in the third it assumed a shooting, lancinating character along the nerves of the neck.

In our first and third cases, one of the early symptoms was an interference with the motor functions. In the first case the interference was of the irritative type; in the latter, of the paretic. The reason is easily explained. In the first instance the tumor was extramedullary, and judging from the absence of pain as an early symptom, it began to grow at the side of the cord and thus irritated either the lateral, crossed pyramidal tracts, or the anterior roots. Judging, however, from the history of the case, we may safely say that the anterior roots and not the lateral tracts were affected. In the last case we were dealing with an intramedullary tumor, where, besides pressure phenomena, the tumor invaded the substance of the cord and destroyed some of its structures. We see here, therefore, that early symptoms were profound paralysis, expressing itself as an early spastic syndrome in the lower extremities, and atrophies and flaccid paralysis in the upper extremities. We could, therefore, justifiably deduct that we were dealing with a lesion that at an early date began to destroy the substance of the cord.

In the third case, one of the early symptoms was visual disturbances. This is readily understood if we remember that high cervical lesions often give nystagmus. The patient, before he gets used to this condition, suffers form visual disturbances. Nystagmus is one of the so-called symptoms that point to a level localization. These localizations are numerous, such as the celiobulbospinal center, sphincteric centers, and so forth. We will not delay at this point to discuss them, as a description of them can be found in any leading textbook. Here, however, a word of caution should be sounded. In giving sensory segmental distributions, the textbooks represent them as sharply defined. At the bedside this is never the case. Indeed, the areas of the various segmental distributions merge into one another. So that, in outlining a segment, space should be allowed on both sides for the adjacent segments.

Physical examination shows objective sensory changes in all three cases. The character, extent, and time of occurrence of these changes varies in each case. In the third case the sensory disturbances occurred early, as evidenced in the history of the case. They were more extensive and dissociated in nature. In short, the early sensory changes in this case were of the tract variety, and only later in the disease were root changes present. Early and profound sensory disturbances accompanied by early trophic and vasometer changes would in themselves speak for a central, *i.e.* intramedullary lesion. In the second case the objective sensory disturbances, while they appeared early, were not so marked, in severity or in extent. They were more of the root type, while tract changes appeared later in the disease. With the appearance of tract sensory changes motor tract symptoms began to take place. Only late in the disease were slight trophic changes seen. It was evident that we were dealing here with a tumor that was pressing on the cord from the outside, and the pressure was exerted somewhere near the dorsal roots. If we take into consideration the Brown-Séquardian distribution of symptoms, we may safely say that the tumor originated on one side of the cord and that it was more toward the dorsum than to the ventrum.

In the first case, the objective sensory symptoms were few and were altogether a negligible factor. Objective sensory symptoms appeared only late in the disease and only toward the end could tract and root symptoms be established. If we now remember that in this case the early symptoms were motor root in type, and that they were unilateral, it will be easy to conceive that we were dealing here with a tumor that was pressing on the ventrolateral part of the cord.

Tract symptoms cannot be used as a guide for level diagnosis; their distribution almost always expresses itself clinically far below the seat of the lesion. They can tell us only how far the cord is compressed, or whether the lesion is primarily within the cord substance. The level diagnosis depends entirely upon the establishment of the highest segmental involvement. This expresses itself clinically either through anterior or posterior root symptoms. The former is rather a rare occurrence, the latter is the usual localization guide. Upon the proper elicitation and interpretation of root changes depends the correct establishment of the level.

In our first case, a wrong level was established in the hospital where the patient was treated prior to his entrance to Montefiore. Here, after repeated and careful sensory examinations, the correct level was finally found. The tumor corresponded exactly to the clinical localization.

As a rule, the mistake is always in putting the level too low. I know of no case where the surgeon has entered above the lesion. The following is offered as an explanation for this mistaken localization: The tumor pressing upon the cord stabilizes a column of cerebrospinal fluid which exerts a certain pressure above the lesion. The pressure of this column causes tenderness along its corresponding roots. The upper level of this tenderness corresponds to the upper level of the stabilized column of cerebrospinal fluid; the lover level corresponds to the highest point of the tumor. If the surgeon would enter at this point (the lower level), correctly discounting the laminæ, we believe that no mistake would be made. Instead, the hyperalgesic belt is at times disregarded and the succeeding belt of anesthesia is taken as a guide. This, while frequently corresponding to the seat of the lesion, may at times be below the lesion. Another mistake is also frequently made. In localizing the segment the surgeon forgets that he counts the spinous processes and not the bodies of the vertebræ. While the relation of the segments to the spine is

always given with reference to the bodies of the vertebræ it must be remembered that the spinous processes of a given vertebra are at least a segment lower than its body and, in the dorsal spine, it is even lower than that. The surgeon must consider this allowance when he establishes his relations between vertebræ and segments. Furthermore, the patient, as he lies on the table with his head hyperflexed, moves his cord up. This explains why the surgeon often finds the tumor by probing above the opening. These are the theoretical explanations for mistaken localization. It is the writer's opinion, however, that a mistaken localization is frequently due to a hasty and unskillful sensory examination and wrong interpretation of sensory charts.

I would like to call attention to an occurrence in our second case. We see that after the lumbar puncture the patient became suddenly more paralyzed and the Brown-Séquardian syndrome became more pronounced. This is due, of course, to the fact that *after a sudden withdrawal of the fluid the tumor pressed more upon the cord and produced the given syndrome.* Such occurrence, I believe, should be considered as pathognomonic of spinal cord tumors where vertebral disease can be excluded.

Fortunately, all the cases in this paper began with unilateral symptoms and only later the entire cord was involved. This is, of course, classical for spinal cord tumors. In another series of cases, however, we will show that the Brown-Séquardian syndrome is not a *sine qua non* for the establishment of the diagnosis of neoplasms of the spinal cord. Such diagnosis should be made whenever there is enough evidence to show that we have, in a given case, a steady, progressive, localized lesion of the cord, and where inflammatory, systemic diseases of the cord, as well as disturbances of the spine, can be excluded. We will not go here into discussion of how to exclude this condition. Such description can be found in almost any good textbook. Whenever we have successively root symptoms, followed by tract and trophic symptoms, an extramedullary tumor should be suspected. When, however, cord pressure symptoms are well established, it is difficult to differentiate between an extra and intramedullary tumor. The diagnosis is then made mainly from the history of the case. A history of early tract disturbances with early trophic changes speaks usually for an intramedullary growth. The classical differentiation of a fixed level in an extramedullary and an ascending level in an intramedullary does not always hold good. Our first case gave symptoms of an ascending level and yet the tumor was extramedullary. Perhaps the most reliable guide is an early involvement of the central gray as evidenced by trophic and vasomotor changes as well as early tract sensory disturbances, which will speak for an intramedullary tumor. The early atrophies, local hemorrhages and extensive analgesias in our third case show such an involvement.

The presence of syphilis in a given case does not exclude the presence of a noninflammatory tumor. Our second case once more emphasizes this rule. Syphilis and a spinal cord tumor may coexist. Whenever we have a well-defined level with pressure symptoms which are not relieved by specific treatment, suspicion of a tumor should always be borne in mind, even though the Wassermann should continue to be positive. Laminectomy to-day is a comparatively simple operation in skilful hands and the patient should not be deprived of the chance of an operation.

Our second case showed xanthochromia with massive coagulation. A few words as to this condition. In 1903 G. Froin (3) reported three cases of spinal cord diseases, two of which were of the pachymeningitis type and one of Landry's disease. In all these cases a yellow cerebrospinal fluid was obtained. Rapid and massive coagulation of the fluid took place almost immediately after its withdrawal. Froin simply recorded the fact without making any generalizations. A number of reports of similar cases soon followed. Derrien, Mestrejat and Roger (4) advanced the so-called lumbar *cul de sac* hypothesis which has become generally adopted. According to this hypothesis, xanthochromia with massive coagulation is obtained whenever the lumbar part of the cerebrospinal cavity is closed off from the general cerebrospinal circulation. The blood vessels of that cavity usually become diseased and permit a transudate into the isolated cerebrospinal fluid. This transudate, which consists of fibrinogen and fibrin, lends the yellow color to the fluid and it is also responsible for the coagulability. D. B. Leitch (5) and a number of others reported yellow fluid in tuberculous meningitis as well as in other known conditions. Spunt and Walker (6), who have studied the subject, came to the following conclusions: 1. A yellow cerebrospinal fluid which does not coagulate is due to dissolved hæmoglobin or its derivatives. It is found in brain tumors which come in contact with the meninges or ventricles. 2. The yellow fluid with spontaneous coagulability is due to a compressed phenomenon. C. L. Mix states further that the presence of an abnormally large amount of cells in the xanthochromic fluid would speak for a meningomyelitic process, granuloma or sarcomatous tumor. Wherever the obstruction is due to a smooth tumor, the xanthochromic fluid will contain a normal amount of cells.

Whether all these niceties are indisputable facts is still difficult to say. So much, however, must be stated. Yellow cerebrospinal fluid always means an organic disease. Xanthochromia with massive coagulation always means occlusion of the lumbar cerebrospinal cavity. Whenever this inflammatory process can be ruled out, xanthocromia with massive coagulability in the presence of level symptoms should always be indicative of a spinal cord neoplasm.

THE MANAGEMENT OF CERTAIN MENTAL AND NERVOUS CASES; A MEDICO-LEGAL ASPECT.*

By DAVID EDWARD HOAG, M.D.,

NEW YORK.

LATE CAPTAIN MEDICAL CORPS, U. S. A.; ADJUNCT VISITING NEUROLOGIST, NEW YORK CITY HOSPITAL, ADJUNCT PROFESSOR, NERVOUS AND MENTAL DISEASES, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL, CONSULTING NEUROLOGIST WEST SIDE HOSPITAL, ETC.

It not infrequently happens that the medical profession is very unjustly criticized by the laity. The doctor, coming as he does into the closest of relationships with the individual and the family, is the target often of much unmerited and unjust attack, and even of needless abuse. He is accused of prolonging his cases, of subjecting them to needless tests, and of paying unnecessary visits. The surgeon has the reputation at times of performing unnecessary operations; the family physician of procuring incompetent and dishonest consultations —all for the sake of a fee.

No one knows better than you and I how utterly untrue and groundless these suspicions are; that such practices may occur in isolated instances, I am not prepared to deny, but I can say in all candor and with all emphasis that I have yet to meet that type of practitioner. Nevertheless, it behooves us all who have to desire to make a wholesome impression on the populace at large—using the popular phraseology of the day—to beware of entangling alliances. The neurologist and psychiatrist, inconspicuous as his work may be, is not by any means immune from criticism of this nature. He is probably more so, since his work is largely among those morbidly inclined.

I have gotten together a few cases that have come under my observation within the last two or three years wherein it was my privilege to act as advisor. I have observed in these cases, as you will notice, a certain judicial attitude, having in mind as I think we all do, or should do, at least, the prevention of any course of action that would prove a detriment to the individual and not be for the best interests of all concerned.

It is the bounden duty of the physician to prevent, so far as possible, the creation in the patient's mind that he has a chronic irremediable condition or disease. I think we all agree on the psychic value of this attitude. Just so, the neurologist should judiciously refrain from pinning the label of an organic disease on his patient, if he can possibly establish a functional cause.

In cases presenting a medicolegal aspect, we should sedulously leave no stone unturned to keep our cases from the ordeal of court procedure. It is this judicial attitude I have attempted to attain. In so doing, I am sure I have kept many individuals off the rocks, so to speak—as well as their friends and doctors too—although I must say that the average practitioner is wise in this respect.

One should keep it paramount in mind that the chief province of the physician in cases of negligence, or where a suit for damages is in mind, is to convince the patient, if it be within the limit of reasonable certainty, that the alleged injury is not great enough to appeal to the courts for adjustment. It is better, I am sure, to err on the side of the defendant than that of the plaintiff. The same rule applies in regard to those upon whom we are called upon to pass an opinion among the mentally afflicted. Although it is our duty to the individuals themselves, their families, and the community at large to protect them from danger—still it is not meant that the offices of our examiners should be used as a short cut to get rid of an unruly member of society.

Goodness knows, our asylums and private retreats are filled to overflowing now, without adding to the burden. It is not long ago since there appeared in the public prints an article in which the writer, who had been in conflict with the lunacy laws and the courts, was attempting to present the evidence of a so-called lunacy trust.

In mental cases one has to be on the lookout for feigned insanity, desire to escape punishment for crime, and for cases of psychic epilepsy. In litigation cases, the accompaniment of an ulterior motive—such as that of revenge, of fear, of financial gain, of desire for a soft berth, for a tangible reason for lack of success in life, for a desire to pose as a martyr, or even it may be an unrequited sexual desire—seeking satisfaction or compensation not always apparent but revealed under investigation.

It is not intended in these pages to minimize the need of careful investigation of all cases of alleged injury seeking adjustment, for many of them are honest and only in search of justice, nor is it meant to convey the hint that we should not subject to a careful scrutiny all cases of alleged mental defect, for the general welfare of the individual and of the community at large must not be lost sight of; but we should strenuously resist the use of our offices in aiding or abetting fraud and deceit.

The first case that I will describe was one referred to me by Dr. C. and seen with him in consultation.

Case I.—A man, 55 years of age, struck from the rear by an automobile which pitched him forward, striking his head against an iron lamp-post and rendering him unconscious. Removed to the hospital, and returned to consciousness in four hours. No appearance of bleeding except from scalp wounds. *X*-ray examination showed fracture of the skull, the line of fracture extending entirely around the skull. The patient made an uneventful recovery. Seen within two weeks after the injury, patient showed perfect orientation. No neurological stigmata. Only thing I suggested at that time was a lumbar puncture, particularly to note pressure of spinal fluid. An eye-ground examination was also suggested. Neither of these procedures was carried out.

A few months later the patient had a convulsion resembling an epileptic seizure, and sought medical advice. He was told that his trouble was probably due to his injury. He then conceived the thought of a lawsuit, not only against the driver of the automobile, but against the doctors who had his case in hand at the time of the injury. Again it was my privilege to act as adviser. The patient's spinal fluid was found to be under very high pressure, as noted by the mercurial manometer, eye-grounds normal. By diplomacy, and perhaps a bit of luck, he has dropped the idea of lawsuit. No recurrence of convulsions in two years—possibly due to the timely withdrawal of spinal fluid.

*Read by invitation before the New York West Side Clinical Society, February 12, 1920; the Brooklyn Neurological Society, April 7, 1920, and the Medical Association of the Greater City of New York, May 17, 1920.

Comment: All cases of head injury should be *x*-rayed; all cases should have eye-ground examination; pressure of the spinal fluid should be noted and a pathological examination of the same be made. Prognosis and advice to patient should be based on these findings.

Case II—Was seen in consultation with the late Dr. J. A. Bodine; may be more appropriately termed a medico-military case. The patient had consulted Dr. Bodine with a self-made diagnosis of appendicitis, and desired an operation. Dr. Bodine found him lacking in some of the features of appendicitis. His past history was not analogous to the chronic type, neither did it conform to the unmistakable distressing picture of an acute attack. Dr. Bodine believed it to be a case of hysteria. Neurological examination of this man of 24 showed a very intelligent, shrewd individual, but lacking the essential stigmata of hysteria. I believed him to be a malingerer, with a motive, which may be often brought to light in a searching investigation, but which was not discernible in his case. Dr. Bodine in his characteristic manner said: "Well, I'll operate on him anyway, since he demands it, and it will do him no harm." Nothing was found either by *x*-ray examination or at operation that was pathognomonic. A perfectly clean abdomen, a perfect recovery from operation, a complete cure of his condition—all his neurotic fears and anxieties having entirely subsided.

The motive for his apparent hysteria was revealed the following year when he appeared before the draft board showing his scar, and expecting fully that it would disqualify him for military service. Finding that it did not, a genuine hysteria developed. By good fortune he came under my observation while I was serving on the Medical Advisory Board of the United States Government. He had learned his book the year before, and now showed all the stigmata of a genuine hysteria. He was a veritable human pincushion. I immediately recommended him for full military service. He was sent back from the first camp, for the reason that while there his symptoms were not only exaggerated, but he had developed an impediment of speech. I again sent him back to the commanding officer with a note of explanation. I later heard of him through the commanding officer at Camp Wadsworth, and the missionary effect of being among real men had had a good result; he became a very good soldier.

Comment: In all cases of a self-made diagnosis where a patient demands operation, watch for the hysterics and be on the lookout for motive. The records show that there were many such cases during the war.

Case III.—Referred by Dr. F. E. Gardner. Dr. Gardner was then in the military service, and he was to return to camp at the time he was notified about this case, so we did not see the case together. The doctor being informed that it was a dangerous mental case, asked me to look after it. Let me say at the start that one gains an insight to many cases, a sort of psychological conception of what confronts him, by the happenings leading up to the first visit. This case illustrates in a sense what I have stated. I received an early morning call on the telephone—an excited demand to come at once; that Dr. Gardner, who was then in the service, had been called back to his post, and that the person was in great danger and that there was need for haste and secrecy. Upon my informing the lady that I could not get there for twelve hours, she replied: "All right, come then."

Arriving at a beautifully furnished apartment at 7 P. M., I was met by a wildly excited French woman, who began gesticulating to me and talking in French. Finding I did not readily understand, she called her brother, who had been guarding the patient, whom I had not yet seen. The story was that the patient—a young man of 25, who was the paramour of the French woman—had tried, so she stated, to murder her the night before. She had waked up finding herself gripped by the throat, and finally managing to get out of the grasp exhausted and breathless and summoned aid. She had black and blue marks on her throat as proof of her statement. She stated that he had been moody, depressed, and irrational all day, that is, the day following the assault, and denied all remembrance of attacking her. She stated that she had known him several months, that prior to this he had been of a cheerful, happy disposition; used to play and sing a great deal; that he was a professional concert pianist; and that his parents were wealthy. She declared that he had suddenly gone insane, and that although they had loved each other dearly despite the disparity of their ages, she being 49, that now she was afraid of him and demanded that he be sent at once to the asylum.

I then went into the adjoining room to interview the patient, much against the protests of the French woman and her brother, who declared it might be unsafe for me to be alone with him. I found a very good-looking young man, athletically built, slightly erratic in manner, but apparently highly educated and intelligent. He held himself in what I believed to be pretended reserve at first, but as soon as he found that I was approaching him in a friendly and interested manner he became less reticent. He stated that he had served two years in the aviation forces; had been honorably discharged from the service, and that he had fallen from his aeroplane several feet, striking on his head, rendering him temporarily unconscious, and that he had had headaches ever since. He declared he knew nothing of the attack of which he was accused, that he loved the woman, and that it was she who was crazy.

Having formed a tentative opinion of his case, I asked him to accompany me to a hospital, which he was willing to do. I told him to get together his belongings, and be ready in half an hour, and summoned a taxicab. When I told the French woman of my plans she made a great protest, that he must not go to the hospital but to the asylum, and that she would at once call the police to take him there. I informed her that the moment she reached for the telephone to summon the police I would also reach for the 'phone and telephone the police department to restrain her from unlawfully attempting to deprive the man of his liberty. The ruse was highly successful. I got away with my man in the cab. I told the driver to go anywhere. I told my patient we were on the way to the hospital. He desired to know what kind of hospital, and I told him the ordinary kind, and that on account of his alleged injury and symptoms I would have him *x*-rayed, blood tested, eye-grounds examined, and spinal puncture made, to all of which he demurred greatly, saying he did not need it, and refusing flatly to go to any hospital. He finally compromised and agreed to go to a hotel for the night and have the tests performed the following day.

You will already note that I was merely sparring for time, and that I had already made my diagnosis, not being that of insanity, but of feigned insanity. Here again it was but necessary to establish a motive, which I already had in mind. I left him at the hotel, under guard of a male nurse, and went back to the apartment of the excitable French woman. I told her she need have no more fear, and then confronted her with the accusation that, realizing that their illicit relations must eventually cease, she had concocted the story of the murderous assault, showing her motive to be that of being able to say to her friends that he had gone insane and that she had to be rid of him, which to a woman of her temperament would not be nearly so humiliating as that he had grown tired of her.

To my patient the next day (I was looking for a confession by this time) I tendered my congratulations on so successfully breaking away from an undesirable liaison—all of which he admitted, and finally confessed that his action was a sham and a pretense, including his effort to mildly choke her. In other words, he made her fear him, which was the only way his weakened and unstable manhood could find to be rid of her. I kept him under observation for some time after that, and finally induced him to go back to his home in a distant city, with a warning as to his narrow escape from being railroaded to Bellevue. According to last accounts he is leading a normal life.

Comment: Be on the alert for a feigned insan-

ity—the motive not being hard to discover, especially if there is a woman in the case.

Case IV.—Referred by Dr. John Van Doren Young. Case of a woman 36 years of age, who had been under intense strain due to war work in Washington. She began acting strangely, depressed, reticent, wandering the streets at night, etc. Her family in New York were notified and she was brought home. She gave a history of a similar attack a few years previously, at which time she had been rushed with great haste to a retreat for the insane. That experience had ever since been a veritable nightmare to her, and she had looked with dread upon any repetition of such treatment. It was first necessary to get her confidence. She was so suspicious that she would not permit me to touch her or even come near the bed. Her past and present history would classify her as belonging to the manic depressive temperament. I kept her in bed with a nurse in charge and under ductless glands medication for two weeks. I finally gained her confidence, and by the aid of the psychoanalytic method—which, although not a routine method of mine, I resort to in some cases—I unravelled a number of sexual aberrations which had a bearing on her case. For four weeks following I kept her almost practically out of doors, walking, bicycling, etc., and finally urged her to become a farmerette. She made a very good recovery.

Comment: Do not commit to an institution except for safety's sake. In a woman, particularly, consider the genadal endocrine picture and analyze the emotions. This girl's brother developed symptoms not unlike that of his sister, but upon investigation they were found to be due to an entirely different cause. They were not due to heredity, but to the environment by which he was surrounded in his business. A change of employer completely restored him to health with but little medical treatment.

Case V.—Referred by Dr. L. Case of a young man, 30 years of age, a musician of more or less prominence, a teacher of music and piano accompanist. His ancestry was unknown, he having been a foundling. Even his foster parents were dead. He lived in the same apartment house, but not in the same apartment, of the young lady to whom he was engaged and who at the time stood sponsor for his care and treatment.

I found the patient bearing the syndrome of dementia precox, with the character of delusions and hallucinations of the paranoid type of that disease. My advice was that this man be removed to a place where a person of his particular mental condition could be kept under observation; and for two other reasons it was necessary: First, that he had no home; and, second, that he must be taken away from the society of the young lady to whom he was engaged.

In looking for motive I read in his case that this was what he desired. The dread of responsibility of matrimony, which is not at all uncommon, had unbalanced an unstable temperament. His friends feared that it would be impossible to take him to an institution except by force; and the other doctor in the case had already made out and signed the commitment papers. I declined to sign, because I do not care to commit if any other way presents itself, for the reason that in many instances it is as bad a handicap in future life as a prison sentence. It is a legal act; it remains forever a blot and a blemish upon a family. Voluntary commitment does not. By a little persuasion I induced this man to so commit himself. He soon became a model patient, and enjoyed the new environment so well that he wanted to try out two or three other institutions, which he did. He was under observation in institutions of his own choosing for over six months, and finally returned to his work. It is now nearly four years and he has had no return of attacks.

Comment: This man was saved the ignominy and disgrace of being committed to an institution where he might have remained indefinitely.

Case VI.—This was a case of litigation in another State, in which I was asked by the attorneys for the plaintiff to examine the plaintiff and testify in court. The plaintiff, a man 26 years of age, was suing a railroad for damages for injuries alleged to have been sustained while a passenger on a train that ran off on a siding, due to a misplaced switch, the train going over an embankment. Patient was said to have a spinal concussion, whatever that may imply. Examination disclosed a condition diagnosed by me as a meningeal myelitis, to which I testified in court. The main symptoms of this condition are pain in the back, unnatural rigidity and stiffness, exaggerated reflexes, partial loss of function of ordinary movement, etc. A day or two before trial the attorney called me on the long distance 'phone and asked if there was anything else that might be done to add strength to the case. Although I felt that there was not, I said offhand that he might have an *x*-ray of the spine. Much to my surprise the picture showed a fracture of the body of a dorsal vertebra, I have forgotten which one, and of the transverse process of the same vertebra.

It is needless to say that he received a very large verdict from the jury. The aftermath of this case came a few weeks later, when I was called to the same city to examine and testify in case of a man hurt in this same accident, also afflicted with the diagnosis of spinal concussion. An *x*-ray picture had been made in this case before I saw the patient and by the same radiographer. By a remarkable coincidence the picture revealed precisely the same injury as in the other case—fracture of vertebral body and transverse process, and even the key-ring that was in the pocket. By this time I began to see daylight and refused to testify.

Comment and moral in this case: Employ only "an honest to goodness" radiographer, or arrange to be present when the pictures are taken. I may say that the first case, in which I had taken a great interest, and had asked the patient to come to my hotel, so that I might advise him to come to New York and consult an orthopedist, since he had a broken back, not only did not put in an appearance, as I had requested, but sent word he was now feeling all right.

Case VII.—Another case of spinal concussion, in which a man in a nearby town had fallen down an elevator shaft, landing on his back. (I get a number of cases of spinal concussion referred to me, I presume, for the reason that my own spinal trouble has been called by my friends among the neurologists and orthopedists as spinal concussion, or at least due to that cause.)

This man was removed to a local hospital, where he was under observation for a few days. No external injury and no bones broken. Sent in to the neurological department of the Polyclinic Hospital, and referred to my service by the superintendent. The patient was disoriented upon arrival at hospital; could neither hear, speak, nor see, and acted so irrationally that the superintendent insisted upon a special guard of nurses and barred windows. I believed this all unnecessary, as it was my opinion that we were dealing entirely with a traumatic neurosis, to which I shall testify in court, as that case is still pending. I may say that speech, sight, and hearing all returned within a few days, due more to suggestion than anything else.

I have no confidence in the traumatic neuroses as a plea for damages in court. I feel inclined to accept the view of Oppenheim, that it is more of a litigation neurosis than anything else. I hope in any discussion that may come up to-night my confidence may be somewhat strengthened.

Case VIII.—Referred by Dr. S.; an unusually interesting case. The patient was a boy of 12 years and gave a history of being struck in the back of the head by a stone thrown by a park employee. It was not intended to strike the boy, but merely to frighten him. The boy fell to the ground and was unconscious for a few moments only. He bled freely from a scalp wound,

which was dressed by an ambulance surgeon, and sent home. He remained up and about during the remainder of the day and for two days afterward.

On the day following, which was three days after the injury, the boy was restless, feverish, and fatigued, and was put to bed. On the following morning he was completely paralyzed in the lower extremities and in one forearm. It was shortly after this that Dr. S. was called to the case. In summoning me he said that he felt that he had a brain injury to deal with, perhaps a fracture of the skull, or at least pressure from hemorrhage. Finding the boy perfectly bright, no stupor, no fever, and with a flaccid atonic paralysis and cold extremities, and reflexes entirely gone, I made the diagnosis of anterior poliomyelitis of the usual onset, and having nothing to do with the injury, but merely coincident thereto. This diagnosis was accepted by the family physician, but rather reluctantly by the family. That the boy might have appropriate treatment, and for other reasons, I suggested that he be sent to Willard Parker Hospital, where the diagnosis was confirmed by examination of the spinal fluid and again corroborated at the Neurological Institute, where he was transferred later.

A short time afterward a lawyer got in touch with me, saying he thought we could easily make a case against the city, as the boy was originally injured by a city employee. I explained to him where he was in error, and nothing further developed. I saw the boy six months later, much improved, but with the residual type of paralysis characteristic of anterior poliomyelitis.

Case IX.—Patient referred by Dr. A. Patient was an Armenian, 42 years of age, with a specific history of long standing. He had been under mixed treatment for a number of years at intermittent periods. History was that the patient had fallen to the floor unconscious and remained so for an hour. Was sent into my service at the Polyclinic Hospital. When first seen by me he was in a more or less stuporous condition, with a well-developed ptosis of the right eye and double vision. The diagnosis was hemorrhage of the crus. The patient, who was then under heavy doses of mercury and potassium iodide, recovered from the stupor, but began to be irrational, loud, and abusive, and threatened suicide, so was well guarded. The patient grew steadily worse, and his private physician felt that he should be removed to a hospital for the insane. Hoping against hope, I called Dr. F. E. Garnder into the case. He was given five intravenous injections of salvarsan by Dr. Gardner at five day intervals. The effect was magical, even from the first dose. The patient made a good recovery, was out of the hospital in two months, and back at his business in three months. The double vision has cleared up, but a slight amount of ptosis still remains.

Comment: It has never been my routine practice to resort to salvarsan in neurological syphilis, but this case and one or two others have revived my confidence in it.

Case X.—I was called by the management of a high-class apartment hotel on the West Side to give an opinion on the mental status of one of their guests. She had taken up her residence at the hotel a few weeks previous to my visit, accompanied by several dogs, a few trunks, plenty of diamonds, and other so-called appurtenances of wealth. Her eccentricities worried the management to some extent. She kept to her room constantly and had her meals served there. She soon engaged a trained nurse and summoned two or three different doctors to treat her. Was continually telephoning friends, day and night, that she was ill and worried, could not sleep, etc. In spite of all this she was giving a great many dinner parties in her room. The night I went there one of these dinner parties was in progress. I neglected to say that one of the principal worries of the management was the fact that they could get nothing in the way of money from this fair patron.

On going to her room the night in question I was escorted into the room by the nurse and elaborately introduced to a goodly company, consisting of, as nearly as I can recall, two lawyers, two doctors, and a few stage celebrities. I was asked to partake of the repast, which I respectfully declined to do. I recognized an old acquaintance in the woman I had been asked to see, although she did not remember me, which may have been subterfuge on her part. Two or three years before this woman had sued her husband for divorce, and in her claim for alimony stated that she was the victim of general paresis, for which her husband had been responsible. I had testified in court at that time not only that she did not have general paresis, but even if it could be proved that she did have it her husband could not have been responsible, for they had lived together but a short time.

To return to the subject of the dinner party—nearly at the close of the repast this woman suddenly threw up her hands, said she was in great pain, and believed she had been poisoned by some of the food or drink. The nurse and one of the so-called lawyers said they felt similar symptoms. The dinner party broke up in pandemonium, the management and the chef having been sent for, and an investigation was promised.

I made a hasty exit, and reported to the hotel management the following day that I considered their guest a professional blackmailer and a dangerous woman. She later proved to be a hotel deadbeat. This particular hotel kept her for a week longer, trying to get their bill paid, but in vain, and finally seized her trunks and ordered her to leave. I understand she went from there to the Gotham, where she was again ordered to leave. She next turned up living in a furnished apartment on Riverside Drive, conducting a school for interpretative dancing. She came to my office about this time, very penitent, saying that she had been unfortunate in certain speculations, but that things looked rosier, and that she would soon pay up all her indebtedness.

She then told me that she had been placed in the hotel from which she had been first ousted by the vice-president of a large corporation in New York, naming the corporation as well as giving the vice-president's name, with whom she claimed to be on very intimate terms. She stated that on the day prior to going to the hotel she had visited him at his office in the building owned by the corporation, and that while descending in the elevator and while making her exit from the same had fallen, striking her head against the iron gate—all of which was due to the carelessness of the elevator operator. She further stated that the vice-president had agreed to look after her, paying her expenses, etc., and that he had not done so. She believed her head had been injured and said that she was going to sue him, asking me to conduct the medical side of the case.

I regarded her as a colossal fraud, and informed the vice-president of my suspicion, and offered then and there to be his witness, if anybody's. The matter died down, some settlement being made. She then drifted out of my sight until during the last year, when she sprang up as a war worker and sought money successfully for many pretended charities. She was arrested, tried, and convicted for fraud, and is now serving time in Auburn.

No comment in this case except that of the proverbial gullibility of New York's native sons No more verdant field for gold-brick speculators exists, far outrivaling the fertile valleys and sloping hillsides of neighboring States.

One more case and I am through.

Case XI.—The private secretary of a wealthy widow, over eighty years of age, came to see me, asking me to visit her employer and give an opinion as to her mental condition. Finding that she had a physician attending her with great regularity I told the secretary I could not do so without his consent and cooperation. This he steadfastly refused to give, saying it was absolutely unnecessary for any one to see her except himself. This woman lived alone with her servants and secretary. She had no children and no known relative anywhere. It had been her habit for many years to go driving daily in pleasant weather, accompanied by her secretary, coachman, and footman. She had often dis-

cussed with the secretary various charities she was going to remember in her will. The secretary noticed that of late she had grown very erratic and hard to please, that she had almost daily conferences with her lawyer and doctor, who always visited her together—the secretary being excluded.

After many years of residence with this woman, and having been given the confidence of a trusted employee, she did not understand, and became very suspicious of this mysterious secrecy. I have no doubt that if this aged woman of wealth were to die suddenly and under unusual circumstances, and especially if it could be proven that she had made a recent will, leaving her money either to the lawyer or the doctor, or both, that the long-devoted and faithful secretary would ask for an investigation by the district attorney's office.

In closing, permit me to say that I claim no originality in the methods employed to make deductions in these cases. I assume furthermore that the assortment of cases described are fairly typical of those found in the practice of anyone aiming to specialize in nervous and mental diseases.

It is merely the application of simon pure psychology—a sort of old-fashioned, common sense, third degree method. It is not psychoanalysis or dream analysis; it is not a struggle with the subconscious; it is possible so to distort the ordinary workings of the mind that one's description may have a so-called psychologic twist, a pseudo-science, but which hypothesis would not be recognized by the academically trained psychologist.

The vagaries of the human mind form an intensely interesting and fascinating study, making it the most attractive field of medicine. To establish a physical cause for mental ills is the recognized province of all neurology and psychiatry. We must be on the alert for manifestations of endocrine disturbances to recognize and eliminate, for instance, the lack of adaptability as well as the presence of fatiguability in cases of hypothyroidism, and in civil legal cases to note, perhaps, the paranoia, querelans type, but we should in no case neglect the moral side, and search for motive, for we are, in a sense, the moral as well as the physical guardians of the people.

To be successful in this one needs to be a combination of seer and prophet, of priest and father confessor, with the wisdom of a Solomon, the discernment of a Diogenes to detect honesty of purpose, the judicial mind of a John Marshall or a Choate, and the detective ability of a Sherlock Holmes.

15 East Forty-eighth Street.

STAMMERING.

UNDERLYING CAUSES AND METHOD OF CORRECTION.

By FREDERICK MARTIN, Ph.D.,

NEW YORK.

DIRECTOR OF SPEECH IMPROVEMENT, BOARD OF EDUCATION OF NEW YORK; DIRECTOR OF CLINIC FOR SPEECH DEFECTS, COLLEGE OF THE CITY OF NEW YORK.

STAMMERING, according to its universally accepted meaning in English, is a halting, defective speech utterance, wherein there is difficulty in starting a word or in passing from one letter to another. It is a momentary lack of control of the muscles of articulation in the effort to speak. At times the stammerer will come to an absolute halt, being unable to produce voice. The defect is often accompanied by irregular spasmodic movements of the face, tongue, neck or body, caused by the effort made to produce a sound or articulate speech.

One form of stammering is commonly known as stuttering. It is the unnecessary repetition of a letter or word before passing on to the next; as, d-d-d-dog, or they-they-they went-went-out.

It is difficult to discover any cogent reason for stammering, for the original causes may be remote, having left only the effect. Something has disturbed the subconscious reflexes necessary for natural speech. There may be a congenital disposition toward a retarded development of speech, but usually, however, cases of stammering ascribed to heredity or phylogenetic influences are due to association with members of the family who manifest some speech defect, or an environment which fosters such weakness. Stammering is at bottom a mental fault which eventuates in a physical disability. It is caused by fear, imitation or improper speech training and is an acquired affection.

Ignorance of this subject is appalling among those who have the care of children. This is due to the paucity of efficient literature. Much has been written on the etiology of stammering, but nothing that gives a dogmatic method of correction. Teachers and parents have been compelled to depend upon the misleading advice of friends who would suggest innumerable panaceas, the majority of which but serve to aggravate the condition.

It has been estimated that three per cent. of our population suffer with acute speech defects. About nine-tenths of one per cent. are stammerers and stutterers. These are a great loss to society, for this handicap retards and perverts some of the best brain power in our communities. It is almost impossible to approximate the cost of stammering. This impediment impairs the mental growth of the sufferer. His self-repression destroys health and happiness which interferes with the expression of ideas as well as the utilization of his potential energy in the business world. With the lack of speech control there is not only less chance for the development of intellectual capacity but a lowering of the moral stamina. Speech differentiates man from the animal and is the greatest weapon of the brain in his fight for success. Business men recognize that the voice is an economic asset, and many firms refuse to employ those suffering from a speech defect. The man who, because of a speech impediment, must repeat an order or a question, causes by his repetition a waste of time which is a financial loss to the employer who, of necessity, demands a brisk, clear cut enunciation.

The indelible impressions made upon the mind of the stammerer by his efforts to speak, increases the physiological cause of his suffering. When laboring under the compulsive idea that he is unable to articulate normally, there is an undue amount of nerve energy released by his brain, in the attempt to control the organs of speech. The muscles laboring under this excessive innervation become rigid, jammed together, and a general juxtaposition results. Should the over-innervation be intense, some of the nerve energy will seek an outlet in other channels, producing tics and spasms. Such tics are seen in the twitching of the facial muscles, contortions of the neck, contractions of the fingers, tapping of the feet, or slapping of the

body. In St. Louis one of the cases brought before me was a boy whose spasms forced him to touch the floor with both hands in the effort to produce voice. These contortions disappeared immediately upon his gaining control of speech and disabusing himself of the paralyzing fear.

Physical obstructions of the air passages seldom bear a direct relation to stammering. They may perhaps, be causal agents through interference with clear enunciation or perfect articulation, but cannot be considered a cause *per se*. Nor does nervousness cause stammering as is commonly supposed. It is the stammering which physiologically reacts to undermine the nervous system, often producing temporary aphasia. The unnatural inhibited speech and the fatigue from undue exertion sometimes produce nervous strain and physical reflexes which affect the habits of the sufferer. However, in such cases the general treatment of the defect and elimination of the immediate causes will restore the patient to normal conditions. The greatest evil, in this great social problem, is the family physician who either tells the parents of a child so afflicted that he will outgrow the defect or else prescribes medicines to cure "nervousness." One is like neglecting a leak in a dam, the other, like stemming the tide with pitch forks.

In New York many prominent neurologists and throat specialists refer all cases of stammering to our special classes. The Neurological Institute is especially active in locating any cases and assigning them immediately to our clinics, realizing that this work is psychological and not medical. As Dr. Walther, a New York nerve specialist, has said, in praising the work of teachers of speech improvement, "This is a field in which our profession has not progressed since the Stone Age." Dr. Wendell C. Phillips, the eminent throat specialist, and ex-President of the Medical Society of the County of New York, states that there is no specific treatment for stammering, that it is necessary to adopt a different method of voice production under competent instruction.

In the correction of speech defects it must always be remembered that each case must be solved as a personal equation. We cannot be generic in our treatment, for as brains differ so the defects arising in these brains will manifest different forms and reflexes which we must learn to detect from individual observation. The teacher's success depends largely on the ability to penetrate the ego of the patient, and to view the difficulty from his angle. Too much sympathy as a prop for his speech is an error. Props merely demonstrate the inability to stand alone. Tears water his seeds of sorrow. The teacher is kindest who makes him prove that he can speak—when she forces him to overcome the handicaps of the class room.

As injudicious advice often aggravates a mild case of stammering, it is well to warn those who come in direct contact with these sufferers of the dangers of many popular practices for their cure.

A common fallacy in attempting to correct a case is to ask the stammerer to take a breath before speaking each word or group of words. The fact that he is made to realize that he must take a breath recalls to his mind his inability to speak as others do. He even recalls the mental picture of his past suffering, and fear predominates to such a degree that all co-ordination of nerves controlling speech is temporarily destroyed. He is obsessed by the compulsive idea, "I cannot say it." It is heresy to attempt to correct stammering by a conscious control of breath. This disturbance is not caused by lack of breath, but because of the interference with the normal subconscious control. There is always enough residual air in the lungs to produce voice. Since the disturbance is mental and not physical, there is no direct relation between the voice and a particular control of the diaphragm. This is proved by the fact that invariably stammerers can sing without difficulty—and singing requires greater lung power than speaking. In the first stages of stuttering the resort to conscious control of breath may help the patient, but in such cases other disciplinary measures would have the same effect without possessing the added element of danger in their application. Some form of diaphragmatic control has been the basis of cure in almost every charlatanistic school or "medical institute" for stammerers.

Suggestion plays an important rôle in the correction of stammering, but will not cure it alone. It is a simple matter to momentarily dispel the sufferer's compulsive fear of speech; but while doing so the various secondary causes which are upsetting his vocal mechanism must be gradually eliminated.

Irrespective of the primal cause, it will be found that 90 per cent. of our cases have not their vocal organs fixed in the correct position for producing the sound which they are attempting to make. A patient may, for instance, try to say "mother," with his mouth wide open—an impossible position for the letter "m," which requires the lips pressed together. When he is made to give this sound correctly, breaking up the remainder of the word into its component parts, or phonograms, he sees that he can produce co-ordination of his vocal organs so as to give each sound in its proper sequence. In the beginning, the process is slow and conscious, but very soon fear of speech itself is dispelled, confidence restored, and a new subconscious control of the organs instituted—all of which makes for perfect speech.

Great care must be exercised to see that the stammerer always opens his mouth quickly for the vowel following an initial consonant. The psychological reason for this will soon become apparent. Exercises containing letters with which the patient has special difficulty or the most fear, should be practised silently, with mirrors, before actual vocalization; thereby focusing his attention upon direct control of the muscles employed.

In my treatments, I use a series of vocal gymnastics which I have carefully developed. The faithful practise of these exercises will not only intensify the auditory images of the stammerer, thus correcting temporary forgetfulness of the sound of the vowels, but will develop stronger vocal chords, producing a new voice and giving a freer control. This will destroy over-innervation or the straining to produce voice.

The correction of an acute case may require the proper training of the emotions to gain self control and relaxation. Relaxation, however, is only efficacious when it can be applied to speech. The

rehabilitation of the mental attitude will alleviate the suffering occasioned by stammering. If the fear of the defect and the consequent secondary causes are removed, the relaxation will be complete and less effort required for speech.

The stammerer needs more rest than the normal person. His efforts to talk are a greater drain upon his vitality and the best therapeutic measure in all cases of fatigue is rest.

DEFICIENT THYROID SECRETION AS AN ETIOLOGIC FACTOR IN GASTRIC AND DUODENAL ULCERS AND IN HYPERACID CONDITIONS.

By JOSEPH KATZ, M.D.,

Brooklyn, N. Y.

It has been long known that disturbed internal secretions are directly responsible for many human ailments, among them also included those of the digestive tract.

Let me here in this paper add another etiologic factor, and at the same time therapeutic measure, in gastric and duodenal ulcers and in any hyperacid condition of unknown origin, viz., deficient or faulty secretion of the thyroid gland. I have come to this conclusion from personal observations and clinical study of this class of cases rather than from laboratory research and will report here a few cases, the results of which inspired my observations in this direction.

Case I.—Mrs. C., 50 years of age, married, has given birth to 8 children. Cessation of menstruation came on gradually at the age of 45 or 46. Family history negative except that a sister is complaining of the same condition as herself. Previous personal history is negative. Present complaint dates back a good many years; constipation, slight heartburn, sudden weak spells. She has seen a number of physicians during the time, each one treating for one gastric condition or another, but none gave her any relief. I have made many analyses of her gastric contents at various times on full and empty stomach, and the results were the same in all, *i.e.*, a high free acidity and a high total acidity. There were no other corroborative factors to denote that the condition was primarily a digestive disturbance. On physical examination, however, I observed on inspection the following, which helped me in making a diagnosis, viz., facies of hypothyroidism or myxedema, slow pulse, at times low mentality; the patient is very obese, although the appetite not of the best; there is swelling of the lower extremities with no pitting. I put the patient on thyroid extract and to my great surprise not only did it improve her general condition which we expected, but entirely reduced her hyperacidity to normal.

This set me thinking whether or not all hyperacid conditions are not due to a faulty thyroid gland. Since then I have seen two other cases of myxedema with hyperacidity which improved under the same treatment. My observations were further corroborated by two other cases, mother and daughter, which I shall here mention:

Case II.—Mrs. K., 40 years of age, has had four children, menses normal; family history negative; personal history negative except for severe heartburn for the last 20 years or so, followed by vomiting which would relieve it for a short time. Inspection revealed nothing abnormal except obesity; other physical examinations negative; gastric analysis showed the expected high acidity. Having ruled out organic disturbance of the gastroenteric tract, including the gall-bladder, I put the patient on general antacid treatment, giving her several alkaline lavages in addition to the general treatment, but her condition did not improve to our mutual satisfaction. I then decided to try the use of thyroid extract in her treatment which proved very beneficial. She continued taking it for some time, in doses of half a grain three times a day, until her condition warranted its withdrawal. The patient has no more pyrosis, although she has not taken any of the treatment for some time.

Case III.—Miss K., 12 years of age, born in the United States, school girl, daughter of the previous patient, began to menstruate at 11. Family history negative except for the mother's complaint as described above. Personal history negative except for pyrosis followed by vomiting after nearly every meal, for the last two years. Inspection showed a well developed girl, obese, and apparently 16 or 17 years of age. She had a great appetite and a great desire for sweets. Physical examination revealed nothing abnormal. Gastric analysis showed hyperacidity. I treated this case also with thyroid extract and the patient has done well.

Having thus observed clinically in the above mentioned cases, a hyperacidity, caused (as proven therapeutically) by a faulty thyroid secretion, and cured or relieved by the administration of thyroid extract, I decided to try the use of thyroid extract in the treatment of ulcers of the stomach, with good results. I desire to report especially one case which has proven my contention and in which the treatment gave marvelous results.

Case IV.—Mr. E., furrier, 42, married, previous history negative; present complaint began about two years ago with pain in the epigastrium after meals, coming on periodically and lasting for about 2 or 3 weeks, till some nine months ago, when the pain became very severe. He had consulted a surgeon of repute, who diagnosed his case as gastric carcinoma and sent him to hospital. *X*-ray plates were then taken and the case was diagnosed as one of perforating ulcer. The patient was advised an operation but refused, leaving the hospital on the same day. He then consulted me and not knowing the diagnosis of either the surgeon or the hospital *x*-ray report, I diagnosed it as ulcer, basing my opinion on the symptomatology and an analysis of the gastric contents. I advised an *x*-ray examination which was made, the report being ulcer. The patient at that time was not fit to undergo an operation and I began treating him with the usual medication for ulcer plus rest, hygiene, etc.; the results, however, were slow in progress, especially so as to pyrosis, as the patient would say, "I am turning into vinegar as Lot's wife into salt." I then decided to try the use of thyroid extract in conjunction with the other treatment and the results were decidedly beneficial. The patient continued to improve daily, his diet is now more liberal, the heartburn has entirely gone, and there is no pain.

This case is one of a number of similar cases that I have treated since with good results.

COOPERATION OF PHYSICIAN AND DENTIST A NECESSITY FOR SUCCESS IN THE TREATMENT OF SYSTEMIC DISEASES.

By RAY R. REED, D.D.S.,

Bay City, Mich.

Chief of Dental Department, Jones Clinic.

The subject of focal infection has brought the medical and dental professions into more intimate relations than ever before. Out of this intimacy have grown two distinct factions: those who uphold focal infection as a valuable addition to science, and those who look upon it as one of the periodical fads which

will meet its death, as so many theories have already.

By cooperation I do not mean the referring to a dentist of patients after medical or surgical treatment has proved futile. What I do mean is cooperation to such a degree as results in routine dental diagnosis. At present this is accomplished in hospitals where dental surgeons are employed and in clinics with dental departments forming an integral part.

I wish to report a few cases which point out the difference between success and failure in the treatment of infectious diseases of possible focal origin.

Case No. 49.—A patient entered with a complaint of throat trouble, pressure, nervousness, insomnia, and headaches. A routine general physical examination was given, and before a diagnosis was extended the dental examination was carried on as a routine. On an *x*-ray of the teeth, impacted cuspids were found to be present. These were removed and the patient made complete recovery.

Case No. 502.—A patient with a complaint of swollen left index finger, showing ecchymosis without previous traumatism, entered on October 18, 1919. The case was diagnosed as endarteritis of the finger. On the extraction of an upper left bicuspid root, and on treating the pyorrhea, the swelling, pain, and other associated symptoms disappeared, and have not recurred.

Case No. 577.—A patient, with a complaint of rope sensation around the waist and pains in all parts of the body, had symptoms suggestive of lues in the third stage, and had had several courses of treatment, in different parts of the country, for syphilis. On presentation, and through routine dental examination, his case was diagnosed as focal neuritis. Ten badly abscessed teeth were extracted and in the course of two weeks the pains, which had persisted for nine years, had completely subsided.

Case No. 650.—A patient with a complaint of persistent urethral discharge, was given a general physical examination and found to have a heart lesion also. Through routine dental examination a mouth of abscessed teeth and pyorrhea was discovered. The teeth were extracted and the pyorrhea treated. This was followed by marked general improvement, which preceded the treatment of the chief complaint.

Case No. 680.—An elderly lady with a goiter and nervousness presented herself for examination. Her case was diagnosed as toxic adenoma of the thyroid and myocarditis. Five diseased teeth were extracted and the pyorrhea treated. She went home for a month. On returning, the goiter had diminished in size, signs of the associated myocarditis and nervousness were markedly lessened, and the systolic blood pressure dropped from 170 to 132.

Cases 49, 502, and 577 are epitomized to illustrate the most valuable point arising from cooperation of the medical and dental professions, namely, routine dental examinations. It is quite evident that without the intimacy, apparent in these cases, the results could not have been attained.

Expect success through cooperation and not after permanent pathological changes are manifest through delayed appreciation of early dental diagnosis. Expect no better results in delayed cases than you would in a metastasized carcinoma.

Case No. 650 shows the value of routine general physical examination. The primary complaint was disregarded temporarily until the general examination was complete. This is cooperation. It is early recognition of these conditions that accounts for the successful treatment of such cases. Had the Neisser infection been treated, without first giving a general examination, the heart lesion would probably have developed into a permanent pathological lesion and become incurable. On the other hand, treatment was started immediately. Following the extraction of the diseased teeth and the treatment of the pyorrhea, marked general improvement resulted. This occurred before the treatment was started for gonorrhea. Do not the results indicate that the patient was benefited by the treatment of the teeth?

Case No. 680 illustrates the value of the method practised by our surgical department, that of eliminating the foci of infection before surgical operations. Whether the conditions are a contributing cause to the chief complaint or not, they should be removed to give the patient higher recuperative power. This woman with a complaint of goiter and nervousness had all infection removed from her mouth and was instructed to go home and return in a month. On her return, the goiter had diminished in size, the associated myocarditis and nervousness had markedly improved, and the systolic blood-pressure had dropped from 170 to 132. Is she not in a more favorable condition for operation than at her first visit? Does this not also show a relationship between focal infection and goiter?

By reporting these cases I wish to bring forth three salient points: First, that of routine dental examinations; second, early reference and diagnosis of cases probably due to foci; third, the value of cleaning up diseased mouth conditions before undertaking surgical treatment.

The supporters of focal infection will obtain success in dealing with it logically. The skeptics will meet with failure, and forever condemn it, by treating it unfairly. Miracles cannot be obtained and should not be expected. Only through the most intimate cooperation and routine dental examination is the doctrine of focal infection, so far as mouth conditions are concerned, to become a valuable addition to modern medicine. Unless it is dealt with in such a manner, it will be branded as a "periodical fad," and meet its fate along with other theories which may be justly termed "fads."

Medicolegal Notes.

Action for Malpractice Limited to One Year in California.—An action against a physician and surgeon for injuries resulting from want of knowledge and unskillfulness is within California Code of Civil Procedure, § 340, subd. 3, requiring the action to be brought within a year.—Kelsey v. Tracy (Cal.), 183 Pac. 668.

Anthrax as an Accident.—The New York Appellate Division holds that where a servant's neck was slightly cut while being shaved at a barber shop, and on the following day, while working in a tannery handling hides, symptoms of anthrax first appeared, his death from the disease was due to accidental injury "arising in the course of his employment."—Eldridge v. Endicott, Johnson & Co., 189 N. Y. App. Div. 53, 177 N. Y. Supp. 863.

Evidence of Good Faith in Dispensing Prohibited Drugs.—The Circuit Court of Appeals, Fifth Circuit, holds, on appeal from the Federal District Court for the Northern District of Georgia, in a prosecution for violation of section 2 of the Harrison Narcotic Act, by selling narcotic drugs, not in pursuance of written orders on the prescribed forms, that evidence that the defendant, although a physician registered under the act, did not dispense the drugs in good faith in the course of his professional practice, which would bring him within exception (a) of the statute, but sold them to gratify the appetite of the purchasers, was competent and relevant, and the issue so made was properly submitted to the jury.—Oakshette v. United States, 260 Fed. 830.

THE MATRIARCHAL FAMILY.

THE grave question of depopulation in France that is frequently discussed in the French medical press is the subject of a striking, though hardly convincing, article by M. P. Carnot in *Paris Médical* of April 17. After pointing out that in 20 years' time the French race will be swept out of existence if French women do not make what he calls a superhuman effort of maternity, M. Carnot very frankly states the actual conditions and their possible remedy. These conditions, already sufficiently serious in 1914, have been naturally much aggravated by the result of the war in depriving the two million unmarried women now in France capable of bearing children of the chance of finding husbands.

To take the place of the men who were killed in the war there are two obvious alternatives: (1) To marry French women to foreigners, a solution that seems to M. Carnot very dubious and one that has had so far no encouragement from the authorities, although it is the only way in which it is possible to secure legal husbands for all French women. (2) To permit polygamy during a certain period —a solution that no one wants and which would probably be useless as a check on depopulation since the high cost of living makes it difficult enough for a man to support one woman, and French families, as well as those of other nations, have for a long time been practising "birth control" on that account.

Before suggesting a third solution, M. Carnot quotes some Danish statistics to prove that in Europe there are now 13,000,000 more women than men, a figure that he believes shows the necessity for the legal recognition of some sort of matriarchal family, composed only of mother and children, of which he reminds his readers that many civilizations have given examples. This matriarchal family would be possible only if it were State supported, and, basing his argument on the fact that the supreme law of a race is not to perish, M. Carnot strengthens his defense by the axiom that in a well-organized society maternity ought to be a woman's career, since, socially speaking, every woman ought to become a mother.

This career for women has never been properly organized, but, he says, it should be both honored and recompensed by the State. The day when maternity is made a remunerative career many women will have children who now hesitate before the expense of bringing them up and the uncertainty of the future. Finally, M. Carnot believes that if it were not for the opposition of public opinion many women would be glad to satisfy their maternal instinct and become the mothers of children who would be their companions in old age. If this be true, the question is largely one of public opinion and economics. Before asking a woman to bear children her future and theirs must be assured by the State. To provide the funds M. Carnot suggests that bachelors and maids who have not fulfilled their social duties to the State should be obliged to leave their money to support the children of those who have.

THE ETIOLOGY AND PATHOGENESIS OF RUPTURE OF THE CIRCULAR SINUS.

THE causes which may produce a rupture of the circular sinus are rather numerous and varied. As to the predisposing factors, the anatomical arrangement of the sinus, the thinness and fragility of its walls, particularly of the wall in relation to the uterine decidua, and its part as a reservoir for receiving the overflow of the maternal placental circulation, are predisposing causes of the first order. If a sudden blood wave occurs, following a uterine contraction forcing the blood from the center to the periphery, the fragile walls of the sinus may give way, and an interesting experimental study would be to determine the necessary pressure for overcoming the resistance of the normal walls of the sinus. A bad insertion of the placenta is yet another predisposing factor and, since Pinard maintains that a bad insertion is not uncommon and is even rather frequent, it can readily be conceived how common a predisposition to rupture must be. In these circumstances the production of laceration of the sinus may be explained as follows: The uterine contractions commence at the fundus uteri and progressively diminish from the fundus to the internal os; there is a mathematical point at which the contraction becomes exhausted. On the other hand, the circulation takes place from below upward, so that it is clear that, maintained by the uterine contraction which prevents it from progressing, as well as by its gravity, the blood accumulates in the declivous portion of the placenta, with the result that rupture of its walls may ensue.

Long-standing endometritis is also a predisposing factor. At the time of pregnancy the lesion may develop an acute exacerbation involving the interutero-placental decidua and from the inflammation a rupture of the sinus results because it is, in reality, simply an emanation of the transformed uterine mucosa. Such instances must be, indeed, rare in practice, as it seems difficult at first sight to admit the possibility of such a lim-

ited endometritis, but nevertheless undoubted instances have been reported. Since inflammatory processes of the serotina are known to exist, it is not difficult to realize the possibility of such ruptures. Finally, multiparity is doubtless a factor because this obstetrical complication is more prone to occur in women who have had a large number of pregnancies.

The determining factors of rupture of the circular sinus are traumata, falls, rough riding, violent emotions, and traction on an accidentally or naturally shortened umbilical cord. Exertion of all kinds, coughing, defecation, or any cause which increases the blood-pressure in an organ with a slow circulation, but having a high vascular tension, may result in rupture of the sinus. It would seem therefore that uterine contraction was among the most important factors in this respect, since it exaggerates the already high pressure in the sinus. But contraction acts in still another manner by causing tension of the membranes whose points of attachment to the sinus may become torn. Rupture of the sinus is more apt to occur during labor at the time when the contractions are frequent and the vascular tension is high.

At the time of labor, when the bag of waters begins to form, traction is exercised by the intermediary of the chorion and decidua up to the margin of the placenta at a point where this organ is nearest to the internal os and the sinus may rupture in consequence. Besides these various mechanisms, it is quite possible that at the time of accidental rupture of the membranes, or during the passage of the child, the tear may extend to the placenta perpendicularly to its margin and not stop until the sinus has been opened. This is probably very uncommon, but its possibility deserves mention. Hemorrhage is sometimes met with, due to rupture of the sinus from some cause which is not apparent. The bleeding is quiet, occurring during sleep, and may be mistaken for a placenta prævia, but the cause is difficult to find. In certain instances, perhaps, sexual relation may be incriminated; also other factors of a general nature producing a morbid change in the vessels, especially of the marginal sinus.

LETHARGIC ENCEPHALITIS.

Economo, who rediscovered this malady and who is in consequence widely quoted in accounts of the same, contributes a long article on the subject in *Il Policlinico*, March-April, 1920, xxvii, 3-4. The author, who saw his early cases in Vienna in the winter of 1916-17, is not an Austrian but an Italian who at present practises in Trieste. His study is very thorough and freely illustrated. His personal material is not very extensive, for it numbers but thirteen cases, all of which are related in much detail. The observation period extended through portions of 1916-17, and no subsequent experience is related. Much space is devoted to the histological changes. The author believes the cause to be the streptococcus of Wiesner, which has a special attraction for gray nervous substance and travels along the lymphatic route. Its point of entrance is probably somewhere in the upper air passages, perhaps the tonsils, by reason of its selection of the lymphatic route through which it reaches the arachnoid space. This seems to have been worked out in the laboratory in connection with experiments on monkeys. A vascular reaction is set up, a proliferation of the adventitia which leads to compression phenomena sufficient to explain the ocular pareses. But while this is only a transitory phenomenon the neurons are also directly attacked and destroyed to some extent, so that actual foci of softening may develop and affect the nuclei of the motor nerves. Apparently these lesions can undergo spontaneous repair. Involvement of the nucleus of the vagus is one of the methods of fatal termination. The parvicellular perivascular infiltration which accompanies the disease is of the type seen in poliomyelitis. The author looks upon cerebral influenza, at least to a certain extent, as a wrongly diagnosticated encephalitis lethargica. The latter, the author believes, may occur sporadically and at times may appear in small epidemics and take on increased virulence.

Netter writes on the first beginnings of lethargic encephalitis in *La Presse Médicale* for April 7, 1920, xxviii, 20, giving numerous references to the early cases of the malady as variously observed. His own first experience was in the winter of 1917-18 at Paris. Economo, as above mentioned, saw his earliest cases in Vienna in 1916-17, and the author again has seen cases in the two winters which have elapsed since the first visitation, the period extending from late in November to some time in February. This is the very interval in which influenza in the great majority of epidemics has appeared. The connection between sleep disturbances and oculomotor symptoms is not peculiar to this affection, for the nerve centers for the two manifestations are in close proximity, and any lesion involving both could conceivably produce the association, as has been shown in the so-called Gayet's disease, which is not lethargic encephalitis. In regard to the so-called "nona" of 1890, this appears to have prevailed in Northern Italy and Dalmatia and to have had very many victims. Both the Italian and Hungarian governments were obliged to take cognizance of its existence, but it was not apparently regarded as contagious. A commission sent to investigate it in one of these countries found that it no longer existed, so that officially nothing was known of it. This in a measure explains our ignorance and the lack of official knowledge of "nona." Netter states that in a few scattered cases there is mention of ocular symptoms, but he is speaking probably of the global incidence of grippal lethargy during 1890, and no locality or reference is given. But of the antiquity of lethargic encephalitits Netter has not the slightest doubt. Aside from the

description of Camerarius in 1712, Albrecht von Hildesheim relates a case seen by him in 1695 in which a young girl of 20 was attacked by fever, headache, somnolence lasting eleven days, strabismus, and ptosis. This was a sporadic case and suggests the failure of authors thus far to consider the possibility that encephalitis lethargica may also have a sporadic incidence. The earliest cases in England occurred three in a family, while the earliest in France were in two men who were working side by side in a ditch.

Perforation of the Nasal Septum from Cocaine Snuffing.

It has been shown by a number of observers that cocaine snuffing, besides the acute or chronic poisoning to which the drug gives rise, may produce local accidents usually consisting of a destruction or perforation of the nasal septum, and it is probable that this lesion is more frequent than is commonly supposed. It usually occurs after repeated and numerous large doses of the drug have been snuffed, and takes place in from six to twelve months' time. Some individuals are perfectly aware of their lesion and sometimes even, as they are in the habit of introducing the finger frequently into the nares to relieve the persisting pruritus, they recall having removed epithelial *débris* by scratching, thus following the evolution of their destructive nasal process. Others are completely ignorant of the lesion and are surprised when informed that a communication exists between the nares. There is no functional disturbance and they only recall that they have had mild epistaxis from time to time. When the perforation has formed it is seated at some point of the septum composed of cartilage, the perpendicular laminæ of the ethmoid and vomer being never involved. The perforation is round or oval and in size varies from a few millimeters to more than a centimeter. In the majority of cases the edges are thin, clean cut, regular, and smooth, as if punched out. In one case the ulceration, which was the starting point of the perforation, was accompanied by fibrous productions similar to small hard polypi. The nasal mucosa is almost always pale and anemic over its entire extent, but it may be just the contrary—red and hyperemic. Usually smooth, it may be the seat of epithelial desquamation and covered by small pellicles. The pathogenesis of the process has not as yet been cleared up. Perforation of the nasal septum is a frequent rhinological lesion, as many causal factors may produce it. Lubet-Barbon does not seem to attach much importance to the necrosing action of cocaine and he is of the opinion that when perforation occurs from its use, the subject is a sufferer of some pre-existing nasal lesion, the cocaine acting as a secondary factor, while scratching is more apt to be the fundamental cause. Hautant accords a greater value to the vasoconstrictive action of cocaine and believes that the continued use of the drug ends by producing a destruction of the anatomical elements of the septum. All observers admit that the vasoconstrictive action is very energetic, and from the resulting intense anemia trophic disturbances are set up, going as far as necrosis of the tissues. On the other hand, scratching may aid the action of the drug by permitting the elimination of the dead tissue and thus becomes an important factor in the production of the perforation.

Scorbutus in the Late War.

Babes brought the subject of scurvy before a medical congress in 1891 when he pronounced it a toxic-infectious disease with a hemorrhagic tendency in which the buccal lesion pave the way for secondary infections. Predisposition is everything, for the disease chooses the weakly and badly nourished, especially those nourished or undernourished with an unbalanced diet. Other groups who suffer are convalescents, puerperæ, half-fed individuals, and those in whom the nervous, gastroenteric, cardiac, and respiratory systems are impaired. Babes continued his study of this affection over a number of years and made many observations—for example one to the effect that Vincent's bacillus and spirochete were often present in the buccal lesions of scurvy, but this proved to be a chance find and later it became apparent that fusiform bacilli in the lesion of scorbutus were not the same as those which cause the other malady. During the present war Babes (*Bulletin de la Section Scientifique de l'Academie Roumaine*, v, 4,) has seen considerable scorbutus in Russian and Turkish prisoners. The patients usually responded very promptly to treatment. The type showed much the same features as in earlier years—weakness, emaciation, ecchymoses, hardness and emaciation of the calf muscles, and blood-effusion in the joints, especially the knees. On the other hand the usual lesions of the mouth and gums were not very marked. There were a few cases of gangrene of the mouth and death from sepsis. The microorganisms of the buccal lesions, had the latter been uncomplicated, would certainly have led to the diagnosis of Vincent's angina, as both spirochetes and fusiform bacilli were represented. The author feels certain that the lesions of the gums made possible the development of sepsis; and while scurvy may from one angle be regarded as a malady of faulty nutrition leading to blood change and hemorrhage, the fact will not down that a hemolytic bacillus might also cause this hemorrhagic diathesis.

"Nona."

When the peculiar form of somnolence known today as encephalitis lethargica appeared in the Northern provinces of Italy in 1889 it received the designation of "nona," a term which has puzzled etymologists ever since. Dismissing outright the guess that it is a lay corruption of coma, we are thrown back on the conclusion that the literal meaning of the word, "the ninth," must first be eliminated. The word "nona" preceded its application to the disease as a vernacular expression, and is said to be used as a generic expression for somnolence. Sampietro in an article on encephalitis lethargica in the *Annali d'Igiene* for January, 1920, xxx, 1, gives a quite plausible etymology as follows: The Northern provinces are given extensively to silkworm culture, and terms technical to this culture are in familiar use. Every eight days or there-

abouts the worm becomes lethargic, or in other words, enjoys a sort of sleep. "The ninth" is therefore the time for sleep and hence used figuratively for sleep or somnolence. Whether or not this statement is biologically correct, it clearly represents a popular belief. The term is therefore a descriptive one which is open only to the objection that the lethargy is not the essence of the malady but only a symptom. No definitions from dictionaries are cited, and apparently the word in this sense has never been passed on by lexicographers and is provincial and colloquial to a notable extent.

Temperature of the Mammæ at the Onset of Lactation.

Guillemet and Vignes have taken the temperature of the breasts of 20 women in a maternity clinic (*Annales de gynécologie et d'obstetrique*, December, 1919, xiii, 10-11). A surface thermometer was fastened to each breast and covered. In 13 cases the temperature before the secretion of milk was 36.3° C., increasing on the first day of lactation to 37.1° C. and then falling slightly. In the other women there was an absence of type. It had already been shown that the temperature of the nursing breast could exceed that of the axilla. Of the 13 women to set a standard all were multiparæ. Secondary rise of temperature was seen in three cases with chapped nipples.

News of the Week.

The Typhoid Death Rate and the Water Supply in New York State.—Figures compiled by the New York State Health Department show that the death rate from typhoid fever in this State has decreased from 19 per 100,000 population in 1906 to 3.3 per 100,000 in 1919, this being the lowest death rate from typhoid fever ever recorded in the State. In this connection the progress made in securing a pure water supply is significant. In 1906 there were some 400 public water supplies which served a population of 6,100,000. About 50 of these supplies received some purification either by slow sand or mechanical filtration, and served a population of approximately 700,000. In 1919 there were 510 public water supplies serving a total population of 8,700,000. Of these water supplies, 125 were purified either by filtration, chlorination, or both, and served a population of about 7,000,000. In other words, the number of people receiving purified water was increased during this period 1000 per cent. The decrease in typhoid fever in this period is almost in inverse ratio to the proportion of people receiving purified water. The State Health Department believes these figures will leave little doubt in the mind of any one familiar with epidemiology as to typhoid fever during this period having been largely waterborne.

Chicago Reduction Class Closes Experiments.—The reduction class which Health Commissioner John Dill Robertson has been conducting in Chicago during the past month completed its experiment on May 20. The greatest loss in weight was scored by Mrs. Susie Jones, who weighed in on April 22 at 224 pounds, and who tipped the scales at only 200½ pounds on May 20. Other members of the class showed losses of 18, 16, 15¼, 11, 10 and down to two pounds.

National Association Opposes Lay Anesthetists.—The American Association of Anesthetists, at its recent meeting in New Orleans, passed resolutions placing itself on record as unalterably opposed to the employment of lay anesthetists, nurse anesthetists, and all other types of anesthetists who shall not have been graduated from recognized medical or dental colleges, and licensed to practise medicine or dentistry. It was further resolved that the American Association of Anesthetists would inaugurate and prosecute legislation to protect the medical and dental professions and the public from such inadequately educated and trained anesthetists whenever such action is necessary.

Dental Society Endorses Health Center Plan.—The New York State Dental Society, at its annual meeting in Albany, unanimously adopted a resolution approving the provisions of the health center bill which was introduced into the last Legislature by Senator Sage and Asemblyman Machold, and laying particular stress on the great need for provision for the proper care of the mouth and teeth of the rural population, and for instruction in the disastrous physical results of neglect to provide such measures. It is estimated that 90 per cent. of children seven years of age are suffering from mouth defects requiring correction. The Life Extension Institute, in 125,000 examinations, found 14 per cent. of those examined with marked infection of the teeth and gums. The resolutions of the Dental Society provide for the appointment of a committee for the purpose of cooperating with all other organizations concerned with or interested in the public health of the State with the view of securing favorable action upon the Health Center Bill at the next session of the Legislature.

Less Crime in New York State.—According to statistics compiled by Charles L. Chute, secretary of the State Prohibition Commission, reports from seventeen of the larger city and county courts in the State for the first three months of the year showed that 43,143 offenders of all ages were arraigned in these courts. During the same period last year 68,535 were brought before the same courts. This is a decrease of 34 per cent., which judges and probation officers are practically unanimous in attributing to the effects of prohibition. In the magistrates' courts of New York there was a decrease of 29 per cent. in the number of offenders brought before the courts. There has been a decrease of 52 per cent. in cases of public intoxication.

Post-Graduate Endowment Fund Makes Progress.—An announcement from the executive committee of the Post-Graduate Endowment Fund states that the fund has been increased by $20,354.77 during the week. This brings the total up to $1,264,801.57 of the $2,000,000 goal set.

Dispensary Appeals for Aid.—The Northern Dispensary, at Waverly Place and Christopher Street, New York, makes a special appeal for funds with which to carry on its work. This institution has given free medical or surgical care to more than one million people in the Greenwich Village section of the city during the ninety-two years of its existence.

Addition to Broad Street Hospital.—The Broad Street Hospital plant is to be enlarged by the addition of thirty beds, a six-story nurses' home, and a new clinic and dispensary. The main structure at South and Broad Streets is to be remodeled and a new building is to be constructed on the adjoining property at a cost of $215,000. The estimated cost of alterations on the main building is $172,000. About $75,000 of the required funds are still to be raised.

Fund in Memory of Dr. E. B. Cragin.—The trustees of Columbia University announce that former patients of the late Dr. Edwin B. Cragin have raised a fund of $3,500 in his memory which is to be devoted to social service work at the Sloane Hospital for Women.

Medical Society Opposes Paternalistic Laws.—The Massachusetts Medical Society of the South Bristol District, at its annual meeting May 6, passed resolutions opposing the passage by the State of paternalistic laws as class legislation and infringing upon the rights of the individual citizen. It considers as tending to universal socialism legislation favoring so-called health insurance, voluntary or compulsory, in all its various forms, including the maternity bill now before the Massachusetts State Legislature.

Sentenced for Selling Narcotics.—Dr. Daniel H. Hoyt, convicted in the Federal District Court on a charge of violating the Harrison drug act by furnishing cocaine to addicts, after being sentenced to four years in the Atlanta penitentiary, was released on $5,000 bail pending appeal.

Dr. Edward H. Cleveland, formerly superintendent of the Hospital and House of Rest for Consumptives, New York City, has become assistant superintendent of the Western Maine Sanatorium at Hebron, Me.

Dr. Theobald Smith, formerly of Harvard University, has been awarded the Douglas Flattery medal and $500 in gold by the Harvard Corporation in recognition of his successful scientific research in the prevention of disease and the conservation of health.

Dr. Q. L. Schofield of Wellesley Hills has received the Cross of the Chevalier of the Crown of Italy for work in the military hospitals at Montove, Italy, where he spent eighteen months in caring for Italian soldiers.

Dr. Herman C. Frauenthal has removed his office to 50 West Eighty-fifth Street, New York City.

National Exposition of Chemical Industries.—The Sixth National Exposition of Chemical Industries will be held in the Grand Central Palace, New York, during the week of September 20 to 25 inclusive. It will be the largest distinctly industrial exposition ever held, and will surpass its predecessors by one-third.

Ohio and Indiana Surgeons Organize.—The Ohio members of the American College of Surgeons met in Cincinnati on May 6, when a State organization was perfected and the following officers elected: *Chairman,* Dr. Charles C. Hamilton, Columbus; *Secretary,* Dr. J. Edward Pierrung, Cincinnati; *Counsellor,* Dr. Walter H. Snyder, Toledo.

A State organization of the Indiana members of the American College of Surgeons was formed at a meeting held in Indianapolis, on May 7, and the following officers were elected: *Chairman,* Dr. Miles Porter, Fort Wayne; *Secretary,* Dr. E. D. Clark, Indianapolis; *Counsellor,* Dr. James Y. Welborn, Evansville.

The Lake Keuka Medical and Surgical Association will hold its annual meeting at Keuka College, Keuka Park, N. Y., on July 29 and 30, 1920.

Child Welfare Congress.—The National Congress of Mothers and Parent-Teacher Associations will hold its annual meeting in Madison, Wis., June 3-8, under the auspices of the University of Wisconsin.

A Move to Discontinue the Bowdoin Medical School.—A circular letter urging discontinuance of the Bowdoin Medical School was recently sent to the alumni of that institution with the request that a reply be given by April 19. In answer to this letter the faculty of the medical school advances the opinion that the matter has thus far had only partial and prejudicial presentation and asks for a suspension of formal judgment on the part of the alumni until the matter can be fairly considered. Reasons favoring the continuance of the school will be in the hands of the alumni before June 22, when the governing board of the medical school convenes.

United Hospital Fund Distributed.—The distribution of the $850,000 fund raised by the campaign of the United Hospital Fund, which aimed to secure $1,000,000, has been completed. Of the amount $400,000 was allotted by the distribution committee in February, being divided among nineteen of the larger general hospitals of the city. The remaining $450,000 goes to special hospitals, nine women's and children's institutions, and six homes for chronics and convalescents. The daily per capita cost of patients in the forty-six hospitals belonging to the fund was $2.02 in 1914; four years later it was $3.20, an increase of 58 per cent. In 1911, 39 per cent. of the patients were listed as free patients. In 1918, only 23 per cent. were free patients.

Gift of a Scholarship to Lyons University.—In *Paris-Médical* of April 24 is announced the gift of 100,000 francs by an American philanthropist, Mr. Douglas Slattery, to the Bacteriological Institute of Lyons. The interest on the 100,000 francs will constitute an annual scholarship for a pupil of the Lyons University, permitting him to devote his time to laboratory work on infectious diseases.

Charitable Bequests.—By the will of the late James B. Rodgers of Philadelphia the sum of $5,000 is bequeathed to St. Vincent's Home and Maternity Hospital. By the death of John M. Walton of Philadelphia bequests of $5,000 each to the Western Temporary Home and the Orthopedic Hospital and Infirmary for Nervous Diseases become operative. By the will of the late Adelaide Albright of Philadelphia bequests are made as follows: Hahnemann Hospital, $30,000, for the endowment of six free beds; Children's Homeopathic Hospital, $18,000, for the endowment of six free beds. Of the residue of the estate one-quarter each is devised to the Home of Our Merciful Saviour for Children and the Protestant Episcopal Hospital for Consumptives.

Medical Society Elections.—THE LITCHFIELD (CONN.) COUNTY MEDICAL SOCIETY, at its annual

meeting in Winsted April 29, 1920, elected the following officers for the ensuing year: *President*, Dr. F. W. Wersebe, Washington; *Vice-President*, Dr. John G. Adams, Canaan; *Secretary*, Dr. Harry B. Hanchet, Torrington.

The Worcester North (Mass.) Medical Society at its annual meeting in Fitchburg, April 27, 1920, elected the following officers for the ensuing year: *President*, Dr. C. F. Woods, Lunnenburg; *Vice-President*, Dr. R. S. Fly, West Townsend; *Secretary*, Dr. C. H. Jennings, Fitchburg; *Treasurer*, Dr. F. H. Thompson, Jr.

The Congress of French-Speaking Physicians of North America has chosen the following officers for its sixth annual congress to be held in Quebec this summer: *President*, Dr. A. Rousseau, Montreal; *Vice-President*, Dr. L. L. Augur, Worcester, Mass.; *Secretary*, Dr. A. Vallee, Quebec; *Treasurer*, Dr. A. Lessard, Quebec.

Obituary Notes.—Dr. George Howard Cantwell, graduate of Jefferson Medical College, and formerly a physician of the Panama Steamship Company, died in Bellevue Hospital, New York, on May 19, aged 51 years.

Dr. Valentine Winters Anderson, a graduate of the Louisville National Medical College, in 1900, died after a long illness, at his home in Dayton, Ohio, on May 10, aged 49 years.

Dr. Robert Norton Downs died at Philadelphia on May 1 at the age of 90 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1856.

Dr. Horace M. White died at Philadelphia on May 4 as the result of a carbuncle. He was graduated from Jefferson Medical College in the class of 1861.

Dr. Alwin Hugo Schwab of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1890, died suddenly while attending a patient, on May 15, aged 52 years.

Dr. Lyndon Bulkley Cady of New York City died in a local hospital following an operation on May 13, aged 32 years.

Dr. Emile Poirier, a graduate of Laval University Medical School, in 1881, died, after a brief illness, at his home in Salem, Mass., on April 29, aged 66 years.

Dr. James Adrian Goggans, a graduate of New York University Medical College, in 1877, died after a long illness at his home in Alexander, Ala., on April 25, aged 66 years.

Dr. Edward Sealey, a graduate of Bellevue Hospital Medical College, in 1884, died at his home in Newark on May 11.

Dr. James Lindsay Porteous, a graduate of the University of Edinburgh, in 1867, died at his home in Yonkers, N. Y., on May 13, aged 78 years.

Dr. Felix Barrett of Westbrook, Me., died after a long illness on April 27, aged 60 years. Dr. Barrett was a graduate of the United States Medical College of New York, in 1883, and of Bowdoin Medical College in 1893. He was a member of the American Electrotherapeutic Association and a former president of the Westbrook Medical Club.

Dr. Wade E. Simpson, a practitioner of Martinsville, Ind., died of heart disease on May 2, aged 42 years.

Dr. C. F. Cushing, a graduate of the Cleveland Homeopathic Medical College, in 1862, died of pneumonia at his home in Elyria, Ohio, May 3, aged 90 years.

Dr. John H. Daniels of Buffalo, a graduate of the Niagara Medical College, in 1895, died after a brief illness in a local hospital, on February 13, aged 53 years.

Dr. Samuel C. Helmick of Commercial Point, Ohio, a graduate of the Miami Medical College, Cincinnati, in 1871, died suddenly on April 29, aged 72 years.

Dr. John R. Prattee of Dover, N. H., a graduate of the Eclectic Medical College, Cincinnati, in 1888, died following a stroke of apoplexy, in a local hospital, on April 27, aged 59 years.

Dr. John Henry Barbat of San Francisco died after an illness of several months, on April 22, aged 57 years. He was a graduate of the University of California Medical Department, a former president of the San Francisco Board of Health and the San Francisco County Medical Society, and a Fellow of the American College of Surgeons.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, May 1, 1920.

The Place of Public Opinion in Preventive Medicine.—Sir George Newman, Chief Medical Officer of the Ministry of Health, is both in precept and practice the main exponent of the principles of preventive medicine as understood to-day in this country. As for many years medical officer of health of one of the big London boroughs, Sir George advanced preventive medicine greatly, and demonstrated by the results of his régime that intelligently conceived and thoroughly carried out measures of prevention were factors of the first importance in promoting good health. As chief medical adviser to the Ministry of Health, he is largely responsible for the plan of campaign of this body and in the Lady Priestly Memorial Lecture, delivered for the National Health Society at the Robert Barnes Hall, London, on April 22, last, he expounded his views. It may be said that the Lady Priestly lecture was instituted for the purpose of organizing annually a public address on whatever subject connected with public health might be considered most important at the time. Sir George Newman said in part that the increase of physiological and pathological knowledge, including that of infection, had been one of the outstanding features of the age. We now knew that disease was not something arbitrary, capricious, occult, or accidental, but was an effect of definite causes and conditions. We also knew that these causes and conditions were in a large and increasing measure controllable by man. To-day, therefore, for the first time, public and personal health had become purchasable. The problem could be stated in a word—the English people were suffering from impaired physique. Ten years of medical inspection in elementary schools had shown that no fewer than 1,000,000 children of school age were so defective as to be unable to derive reasonable benefit from their schooling.

The insurance returns from 1914-16 showed that more than half of the insured persons in England and Wales received medical treatment every year, and that among these persons alone there were upwards of 14,000,000 weeks of sickness a year, a loss of working time equal to 270,000 years per annum—most of which loss was due to preventable sickness. The coming of the Ministry of Health meant a new sort of attack on the strongholds of disease. It meant, of course, increased intervention by the State, improved organization, central and local, a bolder policy. This was good and desirable, but there was a further factor in reform which was in some ways more important than all these, namely, an educated community and an enlightened public opinion. As a nation Great Britain would never win through to a high physical standard until the great mass of the people were educated sufficiently to be able to choose the way of health. Healthy and complete nutrition was infinitely more comprehensive than mere feeding, mere filling of the stomach. It connoted a healthy body in all respects, a brain and nervous system in tone, a healthy muscular and digestive system, circulation of blood and lymph. But when we turned to the dietetic conditions of the great mass of workers, we found a tale of bread and beer, tea and pickles, canned meats and cakes, a bit of bacon and a piece of cheese. Sufficient, appetizing cookery, freshly prepared food, healthy conditions, and sound digestions, these essential things were often absent. The reason was not poverty, but lack of knowledge of the right food to buy and how to cook it. By our ignorance and our willingness to be ignorant, both in theory and practice, we provided the conditions which inevitably led to the growth of a deficient population. All this applied equally to the conditions of health in respect of fresh air and exercise. The advantages of continuous oxygenation of the blood were incalculable, but these advantages were not secured by ill-ventilated schools and factories, or by stuffy dwelling rooms. With few exceptions, the means of ventilation were there. What was lacking was the maintenance of the means by the individual and neglect of maintenance was due to lack of knowledge and to the dominance of bad habit. The lecturer lay stress on the value of games and recreation. He said that the nation ought to have available a complete scheme of education and recreative gymnastics to train both body and brain, combined with games, swimming, field sports and tennis. It was not enough for 40,000 youths to watch a football match; they must also play the game. It was not enough to make provision for physical development for children up to the age of 14 only; it was necessary to carry this on right into adult life. There were few problems more pressing than the provision of facilities for games, athletics, bathing, swimming, and all forms of healthy physical recreation. If we did not solve this problem, at least for the great industrial towns, we must not expect anything but low physique in the population. Nor, must we forget the women, the source of the new race. If music and dancing, golf, hockey and tennis were good for any young woman, they were good for all. Knowledge necessary for the maintenance of health and promotion of sound physique was equally necessary for the prevention of disease. Invalidism, disease and premature death were due to a relatively small number of morbid conditions. A large proportion of these diseases were directly preventable. The chief hindrance in the practice of prevention was lack of knowledge on the part of the public. Sir George Newman then proceeded to discuss the means for educating public opinion, and said that we must avail ourselves of the services of all who know in behalf of all who do not know. The admirable work of the voluntary health societies could hardly be over-estimated, and such a campaign as that represented in National Health Week was particularly valuable. "Why," he asked, in conclusion, "should we not have a 'Health Day' as well as an 'Empire Day,' or 'Hospital Day,' as a regular feature of our national life?"

Science in Great Britain.—Since the war a great deal of enthusiasm has been displayed for scientific education, in which, of course, is included medical scientific education. But money in sufficient amounts is not forthcoming to lead this enthuiasm into practical channels, and enthusiasm by itself does not bring forth much. At the annual dinner of old students of the Royal College of Science, London, held on the evening of April 26, references were made to this matter and to the need for increased financial support being accorded to scientific education and to the value of coordination of effort. Among the medical men present were Sir Richard Gregory, who presided, Sir Alfred Keogh, Sir Ronald Ross, and Sir Frank Heath. In the course of his speech, Sir Richard Gregory said that while technical institutions and universities in Great Britain and the United States received government grants amounting to about £1,000,000 in each case, those in America received something like £6,000,000 from private benefactions alone. Efforts were being made in different parts of the country, especially in Manchester and Liverpool, to arouse local enthusiasm for the work of the universities and higher technical education. It was hoped that these efforts would be the means of inspiring residents and citizens of these districts to offer that support to their institutions of scientific rank that was given so freely in the United States. The Marquis of Crewe, who also spoke, said that at present, with a population of 8,000,000, London had only one university to serve all purposes. The West Riding of Yorkshire and Lancashire, with half the populations, had two universities each, while New York was full of them.

Inspector of Anatomy for Scotland.—The Secretary for Scotland has appointed Dr. Norman Walker to be Inspector of Anatomy for Scotland, and Dr. Francis W. N. Haultain, to be an additional Inspector of Anatomy for a period of two months from that date.

Two Hundred and Twenty-two Nurses Decorated.—The latest figures from the War Department show that two hundred and twenty-two American Red Cross nurses, reserve members of the Army Nurse Corps, have received decorations or citations from the United States and various allied governments for their pluck and high professional skill.

LETTER FROM PARIS.

PARIS, April 15, 1920.

Encephalitis Lethargica.—The séance of the Academy of Medicine that took place last week, presided over by M. Laveran, was occupied by the consideration of the different forms of encephalitis lethargica. M. Vincent advocated the use of the Fochier treatment of injection of turpentine and pointed out that improvement must not be looked for until from 36 to 48 hours after treatment. M. Jeanselene quoted a case in which the paralysis was succeeded by spasmodic contractions of the muscles and discussed whether this symptom should be regarded as a sequel of the malady or a sign of its recrudescence, inclining to the latter theory. M. Achard also spoke of the successive phases of sleeping sickness noticed in the same patient and reported several cases in which, had the history of the phases passed through before admission to hospital not been known, an erroneous diagnosis of hemorrhagic meningitis would have been given. He concluded that these cases should be classed as serpiginous encephalitis. M. Netter, referring to his previous communication on the success of turpentine injections in serious cases of lethargic encephalitis, advocated the generalization of this treatment as soon as the diagnosis is made, and related his experience with nineteen patients, seventeen of whom were rapidly cured by this treament. This subject is very much to the fore in the French medical world. M. Paul Blum contributes a very lengthy article in a recent number of *Paris Médical*, in which he traces the known history of the disease that only made its appearance in France in 1918, and after noting the different publications on this subject, gives a detailed account of all its different phases.

A Shadowless Lamp.—A recent issue of *La Presse Médicale* contains an account of the invention by Professor L. Verain of the "Scialytique," an apparatus for giving light without casting a shadow. This result is obtained by a battery of fifty small mirrors so arranged inside a globe with a 100-candlepower light as to neutralize any shadow cast by the intrusion of an opaque body. The advantage of such a lamp over an operating table will be easily appreciated.

The Teaching of Foreign Languages.—M Léon Azoulay has recently issued an appeal for the teaching of foreign languages in the secondary as well as the primary schools and advocates the exaction of knowledge of at least two languages from every pupil who is a candidate for examination for any profession. The author says: "We insist on this reform because the need for it is most urgent and recent events have induced the powers that be to make practical modifications in every stage of our education. No one can conceive the consequences of such an innovation. Not only will it further intellectual, commercial, and agricultural progress by the information obtained and the emulation provoked, but it will improve our press in making it more scientific and more comparative aud our book trade in impelling it to wider, more useful, and more important enterprises, such as the encyclopedias that are so necessary and issued so cheaply among all classes abroad; besides all this, it would make France the center of the information that Germany was before the war."

Reception to Belgian Medical Students.—A reception was recently given by the medical students of the University of Paris at their delightful "Maison des Etudiants," as they call their students' club, in the old building, No. 13 rue de la Bucherie, that was begun in the fifteenth century and enlarged in the sixteenth for the use of the medical faculty of those days. The soirée was in honor of the eighty Belgian students from the Brussels University who had come to visit their Paris comrades.

Vital Statistics.—Professor Léon Bernard has made a report on "Hygiene and Its Outlook" to the Minister of Public Health. His statistics admittedly are not cheerful. He points out that 1,600,000 men, the youngest and most vigorous of the race, have been slain on the battlefield; that during the four years 1914-1917 the difference between the number of deaths and births shows a deficit of 883,000, and to this must be added 147,000 that corresponds to the country occupied by the enemy during this period. If to these figures are added the deaths whose number in 1918 was increased by the influenza epidemic, there is no exaggeration in putting the total number lost in consequence of the war at 3,000,000. With this premise Professor Bernard traces an admirable portrait of the growth of the attention paid to hygiene and the discoveries made by French savants to whom he pays an eloquent tribute and notes with regret the scanty provision made for teaching this subject in France.

An Anecdote of Landouzy.—His mention of the name of the late Professor Landouzy recalls an anecdote related by one of his friends. Professor Landouzy, whose name will always be associated with the zeal with which he fought the scourge of tuberculosis, was traveling in a first-class carriage when a general in the same compartment began to expectorate profusely on the strip of carpet between the seats. The professor, after enduring this in silence for a few moments, finally asked him to stop, with a few words about the result of his action, whereat the astonished officer, giving the only reason he could suppose for such a request, said, "Have you by chance any shares in the company?"

Progress of Medical Science.

Boston Medical and Surgical Journal.

May 13, 1920, clxxxii, 20.

1. Disturbances Caused by Proteins. J. A. Turnbull.
2. Use and Abuse of Mechanical Supports in Orthopedic Conditions. Herman W. Marshall.
3. The Product of a Urological Clinic. William C. Quimby.

1. Disturbances Caused by Proteins.—J. A. Turnbull discusses hereditary and acquired sensitizations to foreign proteins, and the various ways in which the latter may be produced. He considers more particularly the treatment of hay fevers. In desensitizing patients to the pollens to which they are sensitive, he recommends the injection of small doses of pollen protein solution be begun ten or twelve weeks previous to the pollenating season, and administered every seven days; if treatment is started later the intervals between injections should be shortened. If the injection produces an erythema greater than one-half inch in diameter, the same dose is repeated the following visit; if less, the dose may be increased by one-half to double the previous dose. In some cases it is well to stop treatment previous to pollen liberation; others do better by continuing the treatments during the season. Cases in which there is a continuation of symptoms beyond the pollenating season, due to action of bacterial products, the writer desensitizes with bacterial extracts, using ex-

tracts from which the fats and waxes have been removed, making a solution, and using it subcutaneously. In some cases the continuation of the symptoms may be due to food products. Anaphylactic shock produced by the injection of a greater amount of the sensitive protein than the system can take care of may be relieved in from five to ten minutes by the use of adrenalin chloride 1-1000, giving ten to fifteen minims subcutaneously, intravenously, or intramuscularly.

2. Use and Abuse of Mechanical Supports in Orthopedic Conditions.—Herman W. Marshall emphasizes the importance of braces and mechanical appliances and compares their good features with drawbacks or failures resulting from all other methods. He says it would be possible to collect numerous cases in which massage and exercises have been given too early, or baking has aggravated rather than lessened symptoms, also cases in which surgery has delayed recovery, or plaster casts have afforded too much protection. Other patients who have received electrical treatment for restoration of muscle function have obtained benefit for muscles from the active contractions thus induced, yet the latter have influenced partially united or chronically irritated bone fragments in turn equally harmful. Disproportionate development of any single method to the exclusion of others can be a really malignant tendency at the present time and should be combated increasingly by balanced considerations of the whole field. Braces should not be condemned dogmatically and discarded completely as is so often done because of their obvious limitations. The responsibility for results rests rightfully with the physician rather than with apparatus. The writer sets forth the advantages of mechanical appliances in the treatment of industrial accidents and urges the education of insurance companies to the advantages of medical supports.

1. Influenza as a Pulmonary Necrotic Alveolitis Involving the Endocrines.—Charles E. deM. Sajous submits the following propositions which he believes open a new horizon for the study of influenza, its prophylaxis and treatment: True influenza is due primarily to the Pfeiffer bacillus, but this organism does not provoke its pathogenic effects in the classic manner, that is, in accord with Koch's postulates. When permitted by the defensive mechanism of the respiratory tract to reach the pulmonary alveoli, the Pfeiffer bacillus, finding all suitable conditions for its growth —hemoglobin, oxygen and temperature—therein develops colonies which arrest the function of these alveoli in the respiratory process, and besides cause necrosis of the alveolar walls, of the capillary network underlying the latter, and of the neighboring structures by interfering with their oxygenation and nutrition. The alveolar lesions interfere also with the respiratory process of the system at large, thus causing asphyxia of all organs, including the adrenals, whose hormone enables the hemoglobin to be converted into oxyhemoglobin, and also sustains the tone of the arterioles. The latter being dilated as a result, the general asphyxia is aggravated, while congestion and hemorrhagic foci occur in all organs, including the lungs. The above phenomena give rise to a symptom complex which has been attributed to bronchitis, bronchopneumonia, and lobar pneumonia, but which in reality is that of advanced influenza. The severity of an attack of influenza is proportionate to the number of alveoli invaded by the influenza bacilli, but a mild attack may be converted into a severe one by a secondary autoinfection. Sterilization of the respiratory tract is produced most efficiently by stimulating the lymphoid tissues of the nasopharyngeal area and the mucosa of the entire tract to the bronchioles with iodine fumes deeply inhaled, which promote phagocytosis and sensitize the *Bacillus influenzæ* to the action of these defensive cells. In the treatment of influenza the paramount aim should be to prevent access of the influenza bacillus to the alveoli. Among other prophylactic measures, the writer suggests that carriers be detected with the aid of agar plates, and that they be isolated and treated with iodine fumes and small doses of strychnine and thyroid gland until agar plates indicate that they are no longer carriers.

6. Heredity.—L. D. McEvoy refers to a former article in which the theory of zonal proliferation as a basis of structural variation was advanced as an hypothesis affording an explanation for the phenomena of heredity. The cell as the unit of structure in the zone had parted with a portion of its nerve filaments to the end that an organ might be formed, termed the neural control. This organ by securing cooperation between the zones forming a body, produced the function of coordination between the zones, and could be compared to a governing group of elements, each element retaining control of the zone which it represented, subject to the needs of the body. He now goes on to show that an unbalance in any mechanism of coordination reacts upon the neural control, tending to reduce the power to coordinate to a minimum. The dominant zones, because of the quantitative change in their chemical allotment, become weaker, and this weakness is transmitted to the nucleii extruded by them. When grouped in their container, thrown off by the body and fecundated, the new body formed inherits the loss of virility. The process being repeated may eventually part with the neural control to a more virile group, and an organism is formed retaining the ancestral vestiges of the once powerful combination, now atrophied and inert. A new protective mechanism will take the place of the old following the zonal law; thus zones depending upon the contractile power of muscular elements may establish constriction, or those having a protective armour may adopt a like envelope for the purpose of defense. This theory, he says, reverses the conclusions of Darwin regarding the biogenesis of life, and we can surmise that skeletal remains having relationship with existing species did not advance through successive stages of development, that the processes of environment and natural selection did not produce the distinctive changes in the structure of the cell enabling it to conform to any theory; but, contrarily, the cell had never changed though it might cease to proliferate if the zone of which it formed a part were unable to procure the definite chemical pabulum necessary.

1. The Future of Obstetrics and Gynecology as a Specialty.—Reuben Peterson. (See MEDICAL RECORD, May 22, 1920, p. 887.)

4. The Diagnosis of Epidemic Encephalitis.—Leo Loewe and Israel Strauss have made studies with reference to the value of nasopharyngeal washings and cerebrospinal fluids in epidemic encephalitis. They find that Berkefeld filtrates of nasopharyngeal washings from cases of epidemic encephalitis produce character-

istic lesions when injected intracranially into rabbits. This finding has served them as an aid to diagnosis in 78 per cent. of the cases so tested. A minute filtrable organism, identical with that previously described by these writers, has been discovered in 11 of 17 nasopharyngeal washings cultivated, or 64 per cent. Inoculation of rabbits with the cerebrospinal fluid of patients with epidemic encephalitis confirmed the diagnosis in 12 of 16 fluids injected, or 75 per cent. Cultures of cerebrospinal fluids have been positive in 10 of 20 cases, or 50 per cent. The positive results obtained with the cerebrospinal fluid sharply differentiate this disease from poliomyelitis. Control studies in cases of brain abscess, brain tumor, psychasthenia, and uremia have been uniformly negative.

5. Lipuria Associated with Chronic Nephritis.—Louis Bauman and G. H. Hansmann point out that the several features of this condition which are now more or less well recognized are the occurrence of fat, fibrinogen or fibrin, red and white blood cells in the urine, the direct quantitative relationship between the fat ingested and that excreted in the urine, and the increase in fat elimination during rest in the recumbent posture. They report a case, the clinical, chemical and pathological data of which suggest a progressive nephritis, possibly of syphilitic origin, associated with lipuria and terminating in uremia. The lipuria was influenced by the amount of fat in the diet. The absence of coagulated protein, the scarcity or absence of cells in the urine, and the apparent absence of a fistulous communication, indicate that the lipuria was due to an altered permeability of the renal epithelium. The presence of lecithin and cholesterol was observed. In this case there was no increase of cholesterol in the blood. The occurrence of typical uremic symptoms without cerebral edema or retention of urea which was present in this case has been noted before. The incidence of syphilis in this case leads the writer to recall the work of Stengel and Austin, who noted the frequent occurrence of double refractive bodies in the urine in nephritis associated with syphilis.

9. Specific Nature of the Hemolytic Streptococci of Scarlet Fever.—Ruth Tunnicliff describes experiments showing that the serum of sheep immunized with hemolytic streptococci from the throat in the acute stage of scarlet fever has been found to contain opsonins and agglutinins for the hemolytic streptococci that prevail in the throat and complicating lesions early in this disease, but not for hemolytic streptococci from other sources, such as erysipelas, mastoiditis, measles, influenza, diphtheria, and the normal throat. The results of the absorption tests also indicate that the hemolytic streptococcus from scarlet fever forms a distinct group, scarlatinal streptococci removing the opsinins and agglutinins for these cocci; while absorption from a hemolytic streptococcus from erysipelas has no such effect. The writer believed that these results suggest that the hemolytic streptococci of scarlet fever form a distinct group from the immunologic point of view. The possibility is also suggested that the serum produced with this scarlatinal streptococcus group may prove of use in the diagnosis and treatment of scarlet fever, and eventually perhaps in determining the length of infectivity.

6. Heart-Block: A Record of Twenty Cases. J. Strickland Goodall.
7. Congenital and Hereditary Defects in Recruits: Observations Based on the Medical Examination of 25,000 Men. John Sinclair Manson.

3. The Treatment of Syphilis by the Antisyphilitic Serum of Query.—J. Dobrainsky, J. H. Sequeira, and Theodore Thompson have made a trial of Query's serum in a case of gummatous ulcers of the leg of long standing associated with hyperkeratosis and deafness, and in two cases of tabes dorsalis, which had proved resistant to the recognized methods of treatment. Query's serum is prepared by inoculating monkeys with the filtered cultures of the organism of syphilis in bouillon. When the serum of the monkeys gives a strong positive Wassermann the animals are bled and the serum is collected and preserved in ampoules. The serum was used both subcutaneously and intrathecally. In each of these cases the intractable symptoms yielded to Query's serum in a most striking manner, and in the opinion of these observers the serum deserves a thorough further trial in the treatment of the tertiary stage.

5. Infantile Diarrhea and Vomiting: Their Prophylaxis and Treatment.—G. Douglas Sherwood claims that both diarrhea and vomiting in infants are practically always of infective origin, and that both symptoms, either singly or in combination, can be prevented by antiseptic and aseptic precautions. In the Upwick Vale Home, where an average of seventeen infants are lodged, fed and clothed every year, in the first three years of the institution's existence there was an average of six deaths a year from diarrheal disease. The technique which the author describes was then instituted and for the past twenty-two years no case of diarrhea has originated in the home, and there has not been a single death from that cause. Surgical cleanliness was applied to the nursery both for the prevention and treatment of diarrhea. Emphasis was laid on the following five points: 1. Food was kept in a larder and except at meal times was out of contact with the children and their service. 2. A separate room was used for the changing of the napkins, and where possible a separate nurse for the toilet. 3. The nates were washed with a disinfectant. 4. The nurse's and baby's hands were disinfected. 5. The napkins were immediately placed in a disinfectant.

6. Heart-Block: A Record of Twenty Cases.—Dr. J. Strickland Goodall presents an analysis of twenty cases of complete heart-block, which have occurred in his practice within four years. The main points brought out are the relative infrequency of rheumatic or syphilitic history; the almost invariable association of the condition with mitral regurgitation; the tending to sudden death on gastric distension or exertion; the occurrence of Stokes-Adams "fits" when the heart-block is complete; the frequency of pain as a symptom; the possibility of the condition being transmitted from mother to child; the ability of some patients to work and even to stand severe operations.

1. New Views of the Pathology, Diagnosis, and Treatment of Gastric and Duodenal Ulcer. Arthur F. Hurst.
2. An Address on Surprises in Diagnosis. Edmund L. Spriggs.
3. Results of the Peptone Treatment of Asthma. A. G. Auld.
4. The Myoclonic Form of Epidemic Encephalitis. Piero Boveri.

1. New Views on the Pathology, Diagnosis and Treatment of Gastric and Duodenal Ulcer.—Arthur F. Hurst attempts to answer the question as to what there is about some individuals that make them liable to gastric ulcer, about others that make them liable to duodenal ulcer, and about still others—the majority of people—that saves them from being liable to either. He states that in the average normal stomach the greater curvature reaches to the umbilicus or just below it in the erect position. Considerable variations occur from this in two directions; in some normal individuals the stomach is hypertonic and in others it is hypotonic. In the former the stomach curves obliquely to the pylorus, which is almost its lowest point; in the latter the stomach is hook-shaped and the greater curvature is situated more than an inch below the umbilicus. The hypertonic stomach usually empties itself more rapidly than the average normal stomach, while the hypotonic stomach generally, but not so constantly, empties itself less rapidly. There is reason to believe the hypertonic stomach shows hypersecretion, and that the hypotonic stomach generally shows hyposecretion, *but it may also show hypersecretion.* More recently it has been found

that the stomach in cases of gastric ulcer is generally somewhat hypotonic and almost invariably empties itself more slowly than the average normal. The writer has had the opportunity of examining patients who have recovered from duodenal ulcer as a result of medical treatment, occasionally after many years of complete freedom from symptoms, and has always found the hypertonic, rapidly emptying stomach still present. These observations, in the writer's opinion, prove that the characteristic *x*-ray appearance of the stomach in duodenal ulcer is not due to the ulcer as it is present before the ulcer develops and after it is healed. The same thing is true with regard to secretion, Crohn having found that the curve shows the same hypersecretion and hyperchlorhydria after a gastric duodenal ulcer has healed as it did before treatment began. From these facts the conclusion is drawn that there is one type of stomach in which a gastric ulcer will develop and another type which is likely to lead to ulceration of the duodenum, if the necessary exciting causes are present. An ulcer of the peculiar type found in the stomach occurs nowhere else in the body except in the first part of the duodenum and the part of the jejunum adjoining the stoma of a gastroenterostomy. The one common feature of these situations is the presence of gastric juice. Normal mucous membrane is not digested by gastric juice, but the presence of toxins, the most important source of which is the teeth, may lower the vitality of the mucous membrane. Chemical factors such as alcohol, and mechanical factors such as indigestible particles of food may also irritate the mucous membrane until it becomes less resistant to the digestive action of the gastric juice. The writer is convinced that the tendency to develop a duodenal ulcer is increased by excessive smoking, the nicotine apparently acting through the autonomic nervous system, thus increasing the hypertonus and hypersecretion of the stomach.

3. **Results of the Peptone Treatment of Asthma.**—A. G. Auld has used the peptone treatment in a fairly large number of cases of asthma, and states that his experience has proved instructive in respect to the grouping of asthmatical cases. One group quickly responds to the treatment and the effect is more or less lasting, while the other group is resistant, and is subdivisible into those totally resistant, and those in which, by careful immunization, the disease may be largely overcome. The cases resistant to treatment include nearly all those with chronic bronchitis and developed emphysema, cases presenting any degree of cyanosis, even without bronchitis, and those in whom a more or less oppressed condition of the respiration is never absent. The writer discusses the rationale of treatment and says that since contraction of an isolated muscular organ is only one element in a very extensive picture, and until some more convincing evidence is forthcoming, the anaphylactic shock and peptone shock may be regarded as produced by the identical toxic substance. Immunization by peptone is therefore applicable in cases in which the symptoms may be caused either by whole or split foreign protein. The milder cases of asthma are probably associated with the latter, clinical evidence for which has been recorded, and one attack affords little or no protection. In many of the severe cases of asthma, no doubt, a large molecule operates which is antigenetic, and is succeeded by a period of desensitization. In either case proteose confers on the body fluids a resistance to the induced poison, when used either in small immunizing doses, or in one dose large enough to produce a definite reaction. Non-specific immunization does not possess the independence of action which is the prerogative of the specific (in the bacteriological sense). Hence the necessity, during treatment and thereafter, of a carefully regulated mode of life.

Hygiea.

March 15, 1920, lxxxii, 5.

Two Cases of Total Extirpation of the Stomach.—Sundberg relates the case of a woman of 64 with cancer of the stomach, palpable and of several months duration. Laparotomy revealed diffuse cancerous infiltration of the gastric walls although the organ was movable and without lymph node metastases. Extirpation was subtotal, a small portion of the cardia being used to anastomose with the jejunum (cardiojejunostomy). The patient is living and well 15 months after operation and has taken on weight. The second patient was a woman of 65 with symptoms pointing to cancer for 18 months. Her general condition was good and the tumor while large was movable. Laparotomy showed cancerous infiltration of the gastric wall from pylorus to cardia. Total gastrectomy was performed and an esophago-jejunostomy made with addition of an enteroanastomosis. One week later death occurred suddenly from cerebral hemorrhage. The post-mortem examination showed that the operation had been technically successful.

Il Policlinico.

March 8, 1920, xxvii, 10.

The Cerebrospinal Fluid in Pertussis.—Genoese discusses this subject at length. During the past two years this affection has been especially burdensome in Rome and in certain cases nervous symptoms were so much in evidence that the author tapped the spine. The study of this fluid in this affection is by no means new and a number of finds have been placed on record. Thus far no consensus of opinion exists and no general laws have been laid down. The author tested six cases with the following result: The fluid was always clear and the pressure under which it emerged was above normal. The fact has been established by others in some degree and has been explained wholly on mechanical grounds as a consequence of the raising of the intracranial pressure as a result of repeated paroxysms of coughing. A more modern view is that the toxin of the disease is a stimulant of the secretory function of the choroid plexus. Both factors might conceivably be active at the same time. It has been found that when convulsions supervene the pressure of the fluid shows no added increase. In regard to the qualitative changes the albumin content is normal without the formation of a reticulum, the chlorides are normal, acetone is absent. Boveri's reaction is negative, the cytological examination is negative. There is an augmentation of the reducing substances in the fluid which could plausibly be associated with the increase of pressure. Injections of cocaine and stovaine produce hyperglycorrhachia without any increase of blood sugar and this reaction, Genoese says, is apparently purely mechanical and is due almost solely to the irritation which gives rise to congestionn of the meninges.

Revista Española de Medicina y Cirugia.

January, 1920, iii, 19.

Cosmetics of the Visual Apparatus.—Marquez, an ophthalmologist of Madrid, enumerates a variety of resources beginning with canthoplasties. He reports good results from his modification of the method of Fricke. The Dieffenbach operation he credits *re* priority to a contemporary Spaniard named Argumosa. The justification has been made only by a few Spanish authors, for in general Argumosa is ignored outright. The latter published a work on surgery in 1856 but many years before this period—in 1832—he had performed the operation and received credit for it in the Spanish work on diseases of the eye which was published by Calvo and Martin in 1847. Dieffenbach first operated in 1834 and got into print one year later. The author reports in detail and illustrates cases of Argumosa's operation. Next to canthoplasties he considers operations on the muscles for the correction of strabismus and completes his study by an account of the cosmetics of the globus oculi which deals with enucleation and artificial eye prosthesis. These three categories however by no means exhaust the subject and the author merely enumerates in passing the removal of pterygium, tattouage of the cornea for leucoma, cataract operations considered purely from the cosmetic angle, the supplementary use of glasses in connection with prosthesis—as after strabismus operations, etc., etc.

Book Reviews.

ANAPHYLAXIS AND ANTI-ANAPHYLAXIS AND THEIR EXPERIMENTAL FOUNDATIONS. By Dr. A. BESREDKA, Professor at the Pasteur Institute. With a Preface Dr. E. ROUX, Director of the Pasteur Institute. English Edition by S. ROODHOUSE GLOYNE, M.D., D.P.H., Pathologist, City of London Hospital for Diseases of the Chest. St. Louis: C. V. Mosby Company, 1919.

THE literature on anaphylaxis has developed a tremendous volume and a critical review of it is impossible except to a worker experienced in this particular field. As a result it is exceedingly difficult for the average physician to acquire a simple and clear exposition of the situation as it exists at the present time. Most of the text-books handle the subject in a very scant manner and the majority of the journal articles are confined to very narrow phases of the topic. It is therefore a great satisfaction to have the words of a master in this field written down for us in our own tongue, sufficiently clearly so that all may understand and briefly that all may read but yet with enough detail so that the whole story as it is now known is before us. The translator's work has been well done and he has added a brief chapter which summarizes the work which appeared after the completion of the paper. This small book should find many interested readers.

A TEXT-BOOK OF HUMAN PHYSIOLOGY. Including a Section on Physiologic Apparatus. By ALBERT P. BRUBAKER, A.M., M.D., LL.D., Professor of Physiology and Medical Jurisprudence in the Jefferson Medical College; Formerly Professor of Physiology in the Pennsylvania College of Dental Surgery; Formerly Lecturer on Physiology and Hygiene in the Drexel Institute of Art, Science, and Industry. Sixth Edition. Revised and Enlarged. With 356 Illustrations. Philadelphia: P. Blakiston's Son & Co.

IT is a pleasure to draw attention to a sixth edition of this well known text-book. Having been carefully arranged at the beginning, the successive editions have not shown any very great changes. The book has, however, been kept up to date; the present revision containing new material on carbohydrate metabolism, arterial pressure, and the action of the spinal cord and spinal nerves. Other slight changes have been made throughout the volume, and some new diagrams have been inserted. This book differs from many of its competitors in that it only professes to offer a selection of the more important facts of physiology, preference being given to such facts as will be helpful to students and practitioners of medicine.

LA FATIGUE DE L'APPAREIL VISUEL CHEZ LES OUVRIERS MINEURS. Par le Dr. M. STASSEN. Liege: Imprimerie H. Vaillant-Carmanne, 1914-1919.

THIS volume of 229 pages is a monograph on miners' nystagmus and other disturbances of vision among those who mine coal, as blepharospasm, amblyopia, etc. Numerous short case histories are given and the author controls a material of many hundred cases. There are a number of illustrations comprising lamps and graphics of the oscillations of the eyeballs. The work seems to have been finished or nearly so when the war broke out, so that publication has been delayed five years. The volume is much more than a personal book and is a complete monograph on all the ocular disturbances of miners.

DIE EXPERIMENTELLE BAKTERIOLOGIE UND DIE INFEKTIONSKRANKHEITEN mit besonderer Berücksichtigung der Immunitätslehre. Ein Lehrbuch für Studiernde, Aerzte und Medizinalbeamte. Von Dr. W. KOLLE, Direktor des Institutes für experimentelle Therapie o. Honorarprofessor an der Universität Frankfurt a. Main und Dr. H. HETSCH, Pof. Privatdozent, Oberstabarzt in Sanität-departement des Kriegsministeriums in Berlin. Fünfte, erweiterte Auflage. Berlin und Wien: Urban & Schwarzenberg, 1919.

THIS edition is in two volumes as was its predecessors and contains about four hundred pages more than the third edition. It has been quite carefully revised and apparently embodies the principal changes which have been made during the years of war, at least in Germany. The authors lament their inability to obtain foreign literature and this is plain in scanning their references or in the study of many of their articles. Some little use has been made of English and French work but the work of American bacteriologists and immunologists has been completely ignored. The work retains its character as containing much to point out the practical application of bacteriological findings, and the epidemiological and immunological discussions are exceptionally full. The colored plates are for the most part excellent.

SURGICAL CLINICS OF CHICAGO. Vol. III, No. 4, August, 1919. Octavo of 288 pages with 117 illustrations. Published bi-monthly. Philadelphia and London: W. B. Saunders Company, 1919.

THERE are many interesting clinical lectures in this number, among which may be mentioned those on peripheral nerve surgery, bone and other war cases by Dean Lewis, Nesselrode, Phemister, Ryerson, Pollock, Norris and Reich; A. J. Ochsner's on benign tumors of the parotid; McWhorter's on a case of large sarcoma involving the stomach; and Eisendrath's lecture on methods of examination in the diagnosis of abdominal tumors.

SURGICAL CLINICS OF CHICAGO. Vol. III, No. 5. October, 1919. Octavo of 259 pages with 94 illustrations. Published bi-monthly. Philadelphia and London: W. B. Saunders Company, 1919.

AMONG the more interesting features of this number are a fairly exhaustive discussion by Eisendrath on congenital cystic disease of the kidney and kidney tumors in general; Bevan's clinic on three abdominal tumors, a case of abscess of the pancreas, and a case of ulcerating tumor of the breast; Speed's discussion of the problems of surgical management in duodenal ulcer; A. J. Ochsner's description of the technique of partial gastrectomy, although the Balfour modification of the Polya operation is not mentioned; and Kretschmer's clinic on carcinoma of the bladder and the diagnosis and treatment of bladder stone.

KURZ GEFASSTE PRAKTISCHE BAKTERIOLOGIE für Aerzte und Studierende. Von Dr. L. PANETH, Assistent am kgl. Institut "Robert Koch" in Berlin. Zweite vollig umgearbeitete Auflage der "Feldmassigen Bakteriologie." Berlin und Wien: Urban & Schwarzenberg, 1919.

THE first edition of this handbook was the German war manual of bacteriology. It is very brief and condensed to the most practical and essential details and yet one is surprised to find how complete it is. Such a work will be a convenient means of refreshing one's memory when in the field but it will hardly find a place in the library of the laboratory where more extensive works will be preferred. It is well printed on good paper.

DIE LUMBALPUNKTION. Technik der Lumbalpunktion. Allgemeine und spezielle Diagnostik des Liquor cerebrospinalis. Therapeutische Anwendung der Lumbalpunktion. Von Dr. KARL ESKUCHEN, München-Schwabing. Mit einem Vorwort von Professor Dr. M. NONNE, Hamburg. Berlin und Wien: Urban & Schwarzenberg, 1919.

THE importance of the careful examination of the cerebrospinal fluid has often been emphasized so that there is no need for an apology for the publication of a book on the subject. This book is rather pretentious in its scope, for the author apparently intended to omit nothing from his discussion. The known methods of examination are set forth in detail and following them is a discussion of the findings in the cerebrospinal fluid in the conditions in which it may be abnormal. There is a section on the therapeutic use of lumbar puncture and a brief discussion of the technique. The subject is covered rather thoroughly though there is little evidence that much of the work recorded is the result of the author's own investigations. Comparatively few references are given. The work is more extensive than Levinson's book which was recently reviewed in these columns, but does not show as much original work. It is rather poorly bound.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 29, 1920.

THE PRESIDENT, DR. CHARLES H. CHETWOOD, IN THE CHAIR.

The Diagnosis of Chronic Gallbladder Pathologies.—Dr. ANTHONY BASSLER read this paper. (See page 899.)

The Surgical Consideration of Gallbladder Diseases.—Dr. JOHN F. ERDMANN read this paper. (See page 901.)

Dr. MORRIS MANGES said he had come to the conclusion that he agreed with Dr. Mayo that if one wanted to know the exact diagnosis when there was trouble in the right upper quadrant a laparotomy was the only way in which one could find it out. In making that statement, however, he meant *exact*, and not *approximate* diagnosis. What Dr. Bassler had told them after laying aside the classification and negative evidence, came down to basing the diagnosis upon the history and a sixth sense, and this sixth sense in the last analysis meant keeping in the back of one's mind that sometimes gallstones might exist without occasioning symptoms and that where there were symptoms in the way of ill-defined attacks of increased frequency the disease was advancing. Often too much was taken for granted in the diagnosis of gallbladder disease; there was too much "propter hoc." If a patient gave a certain set of symptoms which the physician seemed to have treated successfully he took for granted that because his treatment was successful his diagnosis had been equally successful. There were a number of conditions showing the same symptomatology, so he felt that they frequently took too much for granted. Dr. Bassler had referred to the Reyfuss tube as of little value in the diagnosis of gallbladder disease. Dr. Manges said he would like to substitute for that the statement that only a small amount of the information which could be obtained by the Reyfuss tube in diagnosis has yet been developed. That its negative value was not much, but its positive value might be very great, as for instance, when there was jaundice and absence of bile one could be quite sure of malignant obstruction, unless there was some anatomical variation from the normal in the biliary ducts or papilla. Studies which he had been making on stomach and duodenal contents by means of the Reyfuss tube had revealed some rather surprising things. For instance, the juice of grape fruit sent a low or normal acidity up to 180. There was a difference in the response of the stomach to such nearly related substances as oatmeal and rice, or the white and the yolk of an egg. We had no idea as yet of the adaptation and response of the gastric mucosa to various substances. He believed that in the future they were going to learn a great deal along these lines, but it was too early as yet to make any definite statements. As to making a positive diagnosis of gallbladder stone by the *x*-ray, he thought that the estimate that a diagnosis could be made in 33 per cent. was rather high; we should be satisfied to have the *x*-ray show motility, deformity, the presence of adhesions, and abnormalities of the stomach and duodenum. That was enough without always asking the *x*-ray to make a diagnosis of stone. In regard to the diagnosis of hypercholesteremia, he thought Dr. Bassler was correct, the good we had obtained from this procedure had not repaid the trouble. Dr. Manges said he was afraid of classifications, as the classification did not usually fit in with the particular case. The chief point to be brought out was that we should remember that there were such things as gallstones and cholecystitis in doubtful cases.

Dr. WILLY MEYER said that when a patient presented himself or herself, complaining of pain in the upper part of the abdomen, we all naturally thought of the stomach, the duodenum, the pancreas, and the gallbladder, but we had learned that the appendix played a great rôle in producing symptoms referable to this region, and also that the symptomatology of the appendix was more frequently combined with that of the gallbladder than with that of other organs. To make a correct diagnosis the most important factor and the one that both Dr. Bassler and Dr. Erdmann had emphasized was a careful history. When there was discomfort or pain in the upper abdominal region, or indigestion, we should think always of gallbladder disease. As aids in diagnosis we had the *x*-ray, the blood cholesterin, and the examination of the duodenal contents. The *x*-ray had not so far given the satisfaction we had hoped from it. Personally he believed that a diagnosis of gallstones in 32 per cent. of the cases by the *x*-ray was a rather high estimate; probably not more than 15 or 20 per cent. of gallstones could be diagnosed by this means. They would probably not improve this percentage until they had learned to make a roentgenogram of the gallbladder and of nothing but the gallbladder. If the *x*-ray showed the stone, all good and well; failure to show the presence of a stone, however, did not mean anything so far as the exclusion of gallbladder disease went. Coming to the use of the Einhorn tubes Dr. Meyer said he had made a very careful study of the duodenal contents and had compared the results with the operative findings, and on the basis of these studies he would have to disagree with Dr. Bassler. He thought the greatest advance that had been made in the diagnosis of gallbladder affections, particularly in the chronic inflammations, was the examination of the duodenal contents by means of the Einhorn tube. It was necessary, however, that the examination should be made correctly. The tube should be left in place, and the nurse should aspirate the contents every half hour. If this was done one would frequently find turbid fluid, cholesterol crystals, pus corpuscles, and absence of bile pigment. The conclusion had been reached that cholecystitis was a much more frequent disease than we had formerly thought. It was a very frequent disease. If one examined the duodenal contents and then during operation aspirated the gallbladder it would be found that the contents of the gallbladder corresponded to the bile found in the duodenal contents. This was important, because if one was operating for appendicitis and found a turbid fluid from the gallbladder in the duodenal content he could then go up and introduce a needle into the gallbladder, and if he found the bile turbid he could go ahead and remove the gallbladder. There were instances in which the failure to do a cholecystectomy in these cases, in the hope that cholecystostomy and drainage would cure the patient, had resulted in chronic invalidism. It was not only the colon bacillus that kept up infection in this locality, but other bacilli as well. He therefore believed that cholecystectomy was better than cholecystostomy. His experience had shown that recovery from cholecystectomy was almost as good as from appendectomy; it was almost 100 per cent. Something unforeseen must have happened if the patient died after the operation. Examination of the duodenal contents, not once but over a number of hours, would give great and important information. If the cystic duct was occluded one would get the discharge from the liver directly, but these were not very frequent cases.

Dr. EDWARD L. KELLOGG said the conclusions of the authors were entitled to respect because of their achievements in their special lines of endeavor. In the consideration of this subject the internist and the surgeon meet on common grounds. The scope of Dr. Bassler's paper did not permit him to tell of his methods of treatment. This was the more to be regretted because many surgeons maintained that these problems were surgical from the beginning; an opinion with which the internist was not apt to agree. The importance of recognizing the less serious pathological conditions was obvious when one reflected that probably most cases of cholelithiasis were preceded by cholecystitis. The less obvious conditions were easily overlooked, and the focal symptoms must be carefully looked for. Deaver suggested that "fair, fat, forty, and belches gas" gave a better idea of the symptoms than the clear-cut picture described in the textbooks. Long ago Moynihan called attention to the early symptoms of gallbladder disease, and particularly emphasized the point that symptoms might be referred to the stomach and not to the gallbladder, and might have a definite relation to the digestive cycle and the character of the food. We must, therefore, search care-

fully for focal symptoms. The *x*-ray certainly was of distinct value. Dr. Kellogg stated that personally he had derived valuable information from studying the bile extracted through the duodenal tube. It was striking to compare the clear, golden bile of the normal biliary tract with the turbid green or dark brown bile, containing flocculent mucus, observed in pathological states, and often this had been the point which had completed the diagnosis. This method had been rendered even more effective by Lyon's suggestion of injecting a solution of magnesium sulphate into the duodenum, and then aspirating the bile, by which he claimed to differentiate the bile from the common duct, from the gallbladder, and the liver. We should not forget the bacteriological study of the speciments, as often valuable information could be obtained. Dr. Erdmann's classical paper was most convincing, based as it was on an almost unrivalled experience. It was natural that the surgeon should see the problem from a different angle than the internist, because his observation started where that of the internist ceased. He was familiar with the failures of medical men, but probably rarely saw their successful cases. Doubtless there was a tendency to keep these cases too long under medical treatment, for which the patients were partly to blame, since they were seldom ready to submit to surgery until the resources of medical treatment had been exhausted. In this connection the laity should be educated to know the possible complications and to understand the importance of resorting to surgery when it was indicated, as they had been in appendicitis. The diagnosis having been made, and the advisability of medical versus surgical treatment being under consideration, Dr. Kellogg said he had formulated for himself this rule: "When in doubt operate." As to the comparative merits of cholecystectomy versus cholecystostomy, he did not believe the last word had yet been said. There was no doubt that in the past some surgeons had left too many gallbladders. Was it not possible that now they were taking out too many? He did not take issue with the leaders of the profession in this matter, but was perplexed by the following questions which, so far as he knew, had not yet been satisfactorily answered, "What is the function of the gallbladder?" "Why do the ducts dilate so markedly after cholecystectomy?" "What is the effect of this dilatation upon the liver function?" "What is the effect upon the individual of the ultimate incompetence of the valve in the ampulla of Vater?" There was no room for difference of opinion in the badly infected, thickened, papillomatous, or obstructed gallbladders, but it was in the lower grades of cholecystitis, perhaps without stone formation, shown by enlargement of the regional lymphatics and thick bile mixed with mucus, that the question arose. In cholecystectomy should the dissection be begun at the fundus or at the cystic duct? The latter procedure was apparently the choice of most surgeons, but did not seem to the speaker to possess sufficient advantages to justify prolonging the operation, as was apt to be the case if the gallbladder was much distended and the liver was difficult to rotate. In fact, in this condition he believed there was a real advantage in starting at the fundus, since this type of gallbladder, when separated from the liver, presented readily in the wound and could be followed down to the cystic duct with little difficulty. In the majority of cases, however, the reverse procedure was preferable. Should the common duct be drained after cholecystectomy? It seemed to him there was an advantage in so doing, as every case of cholecystitis might be complicated by cholangitis. He had found satisfaction with the method used by Dr. Bodine, that was ligating the stump of the cystic duct with No. 1 or 2 plain catgut and using tube drainage, expecting that in two or three days after the area had been walled off by adhesions there would be sufficient absorption of the catgut to permit a free flow of bile from the wound.

Of the two procedures, cholecystogastrostomy and cholecystoduodenostomy, the latter was preferable when possible.

Dr. G. A. FRIEDMAN declared that gallbladder disease was a surgical condition only, and since it was surgical and a very serious disease, it was very important that the physician should know how to diagnose it. Much had been said of the value of the duodenal tube, but this was not accessible to the general practitioner. He thought the value of the tube had been over-estimated by Dr. Meyer, and underestimated by Dr. Bassler; he preferred to take a middle ground. He had before pointed out the importance of pressure points in the intercostal spaces to the right in diagnosing gallbladder pathology, and he never told patients that they had gallstones. He told them they had a diseased gallbladder, for which they would have to be operated upon. If one told a patient that he had gallstones, and then at the operation stones were not found, the patient felt that he had been operated upon unnecessarily and lost confidence. He therefore told the patient, not that he had gallstones, but that he had an inflammation of the gallbladder, and that was a diagnosis that could be easily made, not by the duodenal contents, but in the ordinary routine examination made in every dyspeptic case. One should look for tender spots to the right at the level of the gallbladder, and compare the right with the left side. If there was marked tenderness in the continuation of the right axillary line, scapulary line, the posterior median line at level of gallbladder, one could be sure the case was one of gallbladder pathology and could safely hand the patient over to the surgeon. Gallbladder pathology with or without stones would be found. This search for tender spots could be made by any practitioner. They were present in only one other condition, and that was intercostal neuralgia; they were not present in primary or secondary carcinomas of the liver, or when the liver enlargement was due to pancreatic pathology, or in engorged liver due to cardiac decompensation. It had been said that most patients with cholecystitis had casts and albumin in the urine; he had lost a patient because of that condition which was overlooked. A patient having casts and albumin was given ether and devoloped soon after the operation an ether nephritis and died. Therefore, he thought that every patient sent to the surgeon for gallbladder pathology should have the urine examined for albumin and casts and the anesthetic given accordingly.

Dr. BASSLER, in closing, made a plea for the individual fifty years of age, or thereabouts, in whom all sorts of diagnoses were made—nephritis, arteriosclerosis, cardiac conditions, achylia gastrica, hyperacidity, constipation, etc.—without considering that the symptoms might be related to gallbladder disease. Perhaps the patient only complained of gastric symptoms, still if one kept in mind the possibility of gallbladder pathology and the necessity of paying some attention to it he could be of signal service to some older people. Dr. Bassler said he did not wish to deprecate the use of the duodenal tube, but he did not think it was quite as valuable as Dr. Meyer assumed. He wished to ask a surgical question. He had been making a study of seven cases in which cholecystectomy had been performed and symptoms persisted similar to those from which the patients had suffered before the pathological gallbladder had been removed. These patients showed what Dr. Meyer had described as bile dripping from the common duct; they were discharging grumous bile, débris, and bacteria, and yet they had no gallbladder. He had continued to aspirate these cases until, in one case, he obtained clear, bright yellow bile, apparently from the liver itself. People with a condition like this suffered a tremendous amount of distress, and it was not due to post-operative adhesions. The question was whether in all gallbladder cases there was not disease in the ducts, and whether in doing cholecystectomy one ought not to keep that in mind and make observations with a view of ascertaining whether cholangitis also existed.

Dr. ERDMANN, in closing, said he had intended to say something about the Einhorn tube. Just last week he had seen a patient in whom examination of the duodenal contents had been carried out by means of the Einhorn tube. The case was one in which the symptomatology was so absolutely simple that the diagnosis could have been made immediately on the basis of the history. Dr. Einhorn stated the examination with the tube had shown turbid bile. On opening the abdomen there was absolute constriction and closing off of the duct. Where did the fluid come from?

That brought up the question with reference to cholangitis. In doing a cholecystectomy one did not know whether that procedure was going to prevent cholangitis or not. He cited an instance in which following cholecystectomy a patient had a pseudo-angina pectoris, and it was stated that he had had two attacks of auricular fibrillation. This patient had pains radiating to the shoulder and down the arm, which were probably due to a cholecystitis with stone in the gastric duct. If gallstones were found following cholecystectomy it did not necessarily mean that the surgeon had overlooked these stones. The stones were found because the liver contained stones, and after operation these stones came down from the liver and the patient had to be reoperated. Dr. Erdmann recalled a number of instances in which patients had to be operated upon several times following cholecystectomy for the removal of gallstones. He recalled one case in an immigrant girl of 17 years at the Gouverneur Hospital who had favus and jaundice. On opening the abdomen three stones, as thick as a piece of stick licorice, and each three-quarters of an inch long, were removed, and hundreds of small stones the size of a flaxseed were found. He washed out the entire biliary tract with salt solution, and in less than a year afterwards operated on the girl again and found literally thousands of these small stones. This was a case of hepatic lithiasis. When one remembered that there were such conditions as biliary stones and cholangitis it would be understood that there would be patients who could suffer after operation upon the gallbladder or duct.

AMERICAN MEDICAL ASSOCIATION.

Seventy-first Annual Session, Held in New Orleans, April 26-30, 1920.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 898.)

SECTION ON SURGERY, GENERAL AND ABDOMINAL.

First Day—Wednesday, April 28.

DR. DEAN D. LEWIS OF CHICAGO IN THE CHAIR.

One Hundred Goiter Operations: Mistakes in Retrospect.—Dr. JAMES T. MASON of Seattle, Wash., based this report on one hundred thyroidectomies performed by him during a period of eight years, under morphine and local anesthesia, with the necessary preliminary medical treatment. No bad effects had followed his plan of treatment. Early in the disease it might be difficult to make a diagnosis. In consequence of temporary rapid improvement following the use of various forms of medical treatment many drugs had been considered specific, and surgery had been neglected. The ideal time for operation was in the first six months. The patient operated upon before the first crisis did better than the one operated upon after this. Four-fifths of the thyroid had been removed and the symptoms had disappeared. There was no actual way to determine the amount of damage already done by the disease. All his cases had improved; secondary operations had been necessary in five cases. There were objections to the use of boiling water, and almost always reaction followed ligation. Theoretically, removal of part of the gland should give no reaction. Under local anesthesia he made an incision two centimeters long, dividing skin, platysma, and fascia in the same direction. The fibrous capsule was separated, the field made dry, and the electric cautery passed through down to the anterior surface of the gland, and a piece of the gland about the size of a shoe button destroyed. Vaseline was put on the outside of the wound. Usually there was a little muscular soreness, but otherwise no trouble. This procedure could be repeated every few days, further incisions being made two centimeters apart. This fractional destruction of the thyroid gland by means of the actual cautery in properly selected cases had proved satisfactory in his series of cases.

Diagnosis and Management of Intrathoracic Thyroid Growths (Lantern Demonstration.)—Dr. FRANK H. LAHEY of Boston, Mass., held that too little attention had been devoted to intrathoracic goiter, which could be so satisfactorily operated upon when recognized before the growth had threatened life by obstructing respiration. He classified thyroid growths under two types: those completely intrathoracic, in which no part of the goiter was palpable, as adenomata or cysts of the thyroid, and those incompletely intrathoracic, the lower pole being substernal, subclavicular, or intrathoracic, as in colloid, adenomyomatous, or cystic goiter. The location and anatomy of the thyroid gland were such as to lead one to expect the downward extension of the growth, whereas extension was directly forward. The various factors influencing the direction, and the mechanism of extension were described by the essayist. The clinical features to which attention was especially directed were respiratory obstruction and its periodicity, symptoms suggesting the diagnosis of asthma, and the feeling of substernal pressure. The following diagnostic measures were considered: Roentgen ray (substernal shadow and deviation of the course of the trachea); the inference of malignancy from blurred outline or changed voice; narrowing, distortion, or denting of the trachea on intratracheal examination; percussion dulness; palpation of the apex of the mass in the sternal notch or behind the clavicle. The special points of operative procedure emphasized were the avoidance of morcellation because of bleeding; of leaving behind adenomatous masses; of opening the connective tissue layer surrounding the tumor because of mediastinal infection or hematoma; of bleeding; of injury to the thoracic duct or recurrent laryngeal nerve. In the delivery of the tumor the special points to be observed were the importance of the proper line of separation, pressure with the fingers from below, the amount of force permissible, and division of the sternum. Hemorrhage should be controlled without injury to the nerve. Piecemeal delivery was not to be employed. The dissection of these intrathoracic masses must be within lines of cleavage. Intratracheal, local, or gas-oxygen anesthesia might be employed.

Advantages of Local Anesthesia in Thyroid Operations (Lantern Demonstration).—Dr. JOSEPH R. EASTMAN of Indianapolis, Ind., enumerated the advantages of local anesthesia (procaine and epinephrin), holding that nearly all operations on the thyroid could be performed under local anesthesia with greater safety, greater convenience, and greater precision than under general anesthesia. The advantages were: (1) the accomplishment of hemostasis through the use of adrenal extract; (2) easier dissection of skin flap; (3) greater ease in the delivery of the gland, filling the tissues over and under the gland with the solution facilitating the dissection; (4) by conversation with the patient the operator had a constant check upon such factors as pressure of instruments upon vital structures of the neck; (5) the patient could inform the operator at all times whether the head and neck lay comfortably; (6) gentle handling of the tissues was enforced; (7) postoperative nausea, vomiting, and bleeding were practically eliminated; (8) the patient could take nourishment immediately after the operation. Sensory nerve paths were blocked, no violence was done to heart, lungs, or kidneys, and no injury was done to the recurrent laryngeal nerve, with subsequent impairment of voice. In a limited number of cases general anesthesia presented certain advantages, such as the unconsciousness of the patient, the lessened necessity for gentleness in manipulation, and possibility of completing the operation more quickly, but these were doubtful advantages. The personality of the surgeon was important in operating under local anesthesia, which implied the employment of regional anesthesia in line with the principles of anoci association. The patient need know very little of what was going on, and the terror of the operating room could be removed by proper preparation beforehand. These operations should be left to surgeons of patience and technical skill. It was hardly necessary to reiterate that the prevention of pain after operation should receive the same attention as the prevention of pain during operation. A pillow under the hollow of the back and under the head and neck would reduce the time of operation. Fewer artery clamps were necessary with local anesthesia. Artery clamps should not be left on the neck throughout the operation; it was better always to clamp the vessels, cut between, and ligate.

It was one of the advantages of local anesthesia that the patient protected himself by making complaints of traction or other discomfort. The position of the patient on the table was very important. There should be slight elevation of the trunk, with the neck curved slightly backward.

Technique of Thyroidectomy (Lantern Demonstration).—Dr. WILLARD BARTLETT of St. Louis, Mo., said the Kocher technique or some modification thereof had been employed up to the present time, and it had fulfilled the requirements where the patient had received the proper preliminary treatment. At the same time, the indications for thyroidectomy might be considerably broadened by the employment of a special technique based upon pathological rather than anatomical considerations. In the operation which he wished to present one waived cosmetic considerations, the sole aim being to destroy as much thyroid tissue as possible, which could not be done under other technique. It was an emergency operation, giving the most direct and bloodless approach to the tissues, saved the time spent in ligation, shock was rendered unlikely because the operation was short, the nerves were blocked and very little traction was made. Likewise, postoperative thyroidism was not to be expected, absorption not taking place, the wound being left wide open. This emergency tecnique was intended for the relatively small number of doubtful cases in which no guarantee of safety could be given after classical thyroidectomy. In many toxic adenomata the patient was so sick that the classical Kocher operation was not satisfactory. The preparation of the patient for this emergency operation was the same as under other circumstances. As soon as the patient had reached the maximum improvement she was taken to the operating room, the head of the table was slightly elevated, the face was turned away from the operator, and the site of the incision was marked out just posterior to the anterior border of the sternomastoid muscle. The incision was then made over the most prominent part of the lobe, forgetting all cosmetic considerations. There was no need for touching the jugular. A diamond-shaped area was infiltrated by two needle punctures. The operation was done in two sittings for the reason that the patient's strength was not sufficient for the completion of the operation at one. As such a patient must not be kept long on the table it was well not to wait for complete nerve block, but to proceed with the operation as soon as possible after the patient was placed on the table. The incision allowed one to approach the tumor by the most direct route. Fewer vessels were encountered than by the so-called collar incision, and the resulting scar would lay upon a performed ridge on the sternomastoid muscle. As soon as the skin incision was made sutures were introduced, to be tied later, then held out of the way by an automatic spreader. After gentle retraction the sternomastoid muscle was split longitudinally; it was seldom necessary to cut in any other way than longitudinally. In this technique the upper pole of the gland lay squarely exposed in the incision. A slight amount of traction would give all the exposure necessary. The exposed lobe was now caught with light clamps and lifted gently. The whole area was flooded with alcohol, and as a further precaution against absorption the furrow around the gland was often packed with dental cotton, provided there were room enough. The upper pole was then divided, the capsule and goiter substance divided. It was relatively easy to gently snip out the upper pole, provided there were no perithyroiditis. If adhesions had to be broken up a whiff of gas might be given. He left a few clamps in very sick patients; where the patient was not so sick he left the wound wide open. He had left as many as thirty-four clamps in experimenting to see how many the patients could bear.

Dr. HENRY S. PLUMMER of Rochester, Minn.. opened the discussion on these four cases. It was difficult to diagnose substernal goiter. The risk of postoperative hyperthyroidism varied with the stage at which operation was resorted to.

Dr. EMIL GOETSCH of Brooklyn, N. Y., asked Dr. Mason why he preferred to use the cautery repeatedly instead of ligation. Reduction in partial thyroidectomy was either reduction of gland substance or reduction of vascularization. He could not see, on theoretical grounds, why one should do repeated operations which were certainly more mutilating than ligation. In exophthalmic goiter one could not say that there would be a crisis six months later; one could not predict. Referring to Dr. Lahey's paper, the speaker said one must remember that in some instances these growths were accessory thyroids, a point to be considered in the etiology of these tumors. He did not see why one should go back to local anesthesia in toxic cases, when one could use gas and oxygen with anoci association. It was not unusual to see a pulse of 140 to 150 fall to 110 or less and remain so throughout the operation. This would seem to be an index to the toxicity, which seemed to be less with gas and oxygen.

Dr. E. G. JONES of Atlanta, Ga., referring to the amount of tissue to be removed, said operators of today had profited by the experience of the pioneers, with the result that they were troubled very little with so-called recurrence. Dr. Bartlett's technique was important in helping to handle these very unsatisfactory cases in a satisfactory manner. It might not be satisfactory from a cosmetic point of view, but that was a minor consideration. Whether one employed local or general anesthesia the anoci association should begin the first time the patient was seen. During the entire time of care the patient should be relieved of all factors which militate against the success of the operation. The speaker called attention to the relative rarity of goiter in the South as compared with its incidence in other parts of the country.

Dr. A. J. OCHSNER of Chicago thought a great deal of comfort would be derived from Dr. Bartlett's views. There was no good reason for leaving on the clamps. He had compared hundreds of cases of both local and general anesthesia, and as a rule the patient who had been operated on under local anesthesia was less badly off than the one who had been operated upon under general anesthesia. As a rule he performed all goiter operations with local anesthesia provided the patient was not excessively afraid of it. Referring to Dr. Lahey's remarks concerning subclavicular goiters one point should be emphasized, namely, that a sharp cough might burst the pleura. To prevent this he immediately put a moist sponge in the place of the goiter immediately after its removal, then proceeding with the operation. The explanation which Dr. Lahey had given concerning the goiter being pressed down by the strong muscles was plausible. When degeneration of the heart had once occurred in hyperthyroidism this would not be overcome. In order to avoid degeneration of the heart one should operate early.

Dr. CROTTI had operated so far in more than a thousand cases and he considered ether and oxygen the best anesthetic. A few fundamental principles should be borne in mind. One must have a complete knowledge of the anatomy of the region; one must be sure that he is operating in the right line of cleavage, and no attempt should be made in intrathoracic goiter to remove the gland until the upper pole has been ligated and the whole isolated. One must work very gently around a goiter. In the presence of bronchitis or catarrh local anesthesia should be used; when no such condition existed general anesthesia could be used.

Dr. HARRIS considered nerve blocking in thyroid operations one of the most satisfactory procedures in surgery. It could be accomplished by a single needle puncture on either side of the neck, the entire side of the neck being anesthetic, so that any operation could be done upon it without pain. Under complete blocking the patient would arrive upon and leave the table in better condition than under general anesthesia, there was less secretion in the trachea, and the time of recovery was shorter.

Dr. GEORGE W. CRILE of Cleveland, Ohio, held that there were objections to the use of local anesthesia alone or to general anesthesia alone. In toxic goiters there was interference with respiration, consequently all inhalation anesthetics interfered with oxidation. With local analgesia with gas and oxygen there was not this interference with oxidation. In certain cases he had allowed the wound to remain open in order to prevent toxic absorption and because the patient was more comfortable. On all sides operators had come to realize the importance of conserving in every way possible all the factors of the patient's resistance. The

perfection of the technique of administering anesthetics, whether local or general, had made possible great progress in the surgery of goiter.

Dr. MASON, in closing the discussion, replied to Dr. Goetsch's question as to why he preferred repeated excision to ligation by reiteraing that he employed repeated excision when he felt that the patient was not a safe risk for ligation. He cited a case in which the patient had had three excisions. The large percentage of cases that had to be reoperated were the earlier cases operated upon six or seven years ago.

Dr. LAHEY, in closing, reiterated that if the trachea be dislocated to one side there must be an intrathoracic growth. In difficult cases where the delivery of the gland was accomplished only by manipulation he did not see how it was possible to prevent injury of the recurrent laryngeal nerve. He thought the patient should be warned beforehand of the possibility of such injury.

Dr. EASTMAN, in closing, considered local anesthesia of great value and especially applicable in bad cases. The man who habitually employed local anesthesia, as a routine method in goiter operations, would be better prepared for its use in serious cases in which it was demanded. There was local anesthesia and local anesthesia—the local anesthesia as employed by one who uses it habitually, and that as employed by the man who uses it in a patronizing manner when the seriousness of the cases demanded it. Especial attention was called to the very trifling detail of making slight compression of the skin for the first introduction of the novocain, thus preventing pain with the introduction of the hypodermic needle. By attention to this small detail one could prevent the destruction of the patient's confidence at the very outset. The thickening of the panniculus adiposa greatly facilitated the operation. The elevation of the lobe upon the water-bed facilitated the shelling out of the growth. He left no clamps upon the neck during the operation.

Dr. BARTLETT, in closing, referred again to the importance of the incision just behind the sternomastoid, the notation of the anatomical details, the absence of injury to the jugular and the recurrent nerve, the infiltration of the diamond-shaped area, the use of the little spreaders, exposure and splitting of the ribbon muscles longitudinally, the exposure and opening of the external capsule, the pouring in of the alcohol, the lifting up of the goiter and the application of the clamps.

Chronic Cystic Mastitis (Lantern Demonstration).—Dr. JOSEPH C. BLOODGOOD of Baltimore, Md., made a pathological grouping of the cases of mastitis, based on the tissue removed at operation, as follows: (1) Breast the seat of disease with large blue-dome cysts of the galactocele type, (2) Breast the seat of disease with no large blue-dome cysts of the galactocele type. He further subdivided the cases of this group into those with areas of adenomatous hyperthrophy only; a few small cysts or few dilated ducts, or both; and dilated ducts only. (3) Chronic cystic mastitis resembling the description given by Schimmelbusch and Reclus, or the adenocystic type of senile parenchymatous hypertrophy described by the essayist. (4) Chronic cystic mastitis of the Schimmelbusch type, with mitotic areas suggesting early carcinoma (adenocarcinoma in chronic cystic mastitis). (5) Breast the seat of fully developed carcinoma with surrounding chronic cystic mastitis. (6) Breast the seat of distinctly beningn lesions with surrounding chronic mastitis. Emphasis was given to the observation that cases presenting these blue-dome cysts were benign. This finding was a better indication of a benign lesion than any other gross or microscopic finding. On nicking the dome of these cysts the color disappeared and the contents flowed out. The fear of cancer caused some surgeons to remove the breast which was the seat of chronic mastitis. When they found little cysts or dilated ducts from which they could express yellow, brown or green fluid, they were inclined to remove the breast, on the ground that this chronic cystic condition might be an etiological factor in the production of cancer, or that if left the danger of cancer was increased. He knew of no fact to demonstrate that this fear was based on fact. The earlier observations of Schimmelbusch, Reclus and the essayist, which gave the impression that at least fifty per cent of the cases of chronic cystic mastitis were associated with cancer and had not been borne out by later observations and experience. The clinical grouping of the cases, included, first the various clinical pictures given in the pathologic grouping present before operation, and second, cases presenting identical clinical pictures observed in Group 1, not subjected to operation.

Dr. WILLIAM C. MACCARTY of Rochester, Minn., had seen many cysts of the breast described by Dr. Bloodgood, but whenever he had seen such a cyst he had also wanted to see the other gland structures because he had seen cancer the size of a pin head two or three centimeters from the cyst. He had also probably missed such a cancer because formerly he had depended upon the gross examination of the breast. To-day he would submit every portion of a breast with such a cyst to careful microscopic examination. Any breast, it made no difference what the gross appearance was, whether there was one or a dozen cysts, regardless of the size of the cysts, should always be examined with the microscope. He had seen cysts removed and the patient come back with cancer of the breast. He considered cysts in the breast more dangerous than Dr. Bloodgood had led one to believe.

Dr. BLOODGOOD, in closing the discussion, said Dr. McCarty's position and his narrowed themselves down to the matter of taking out or leaving in the breast with these cysts. The speaker's series of 329 cases of chronic cystic mastitis with two deaths from cancer seemed to him a good argument in favor of the "leave it in" policy. He would not say that cancer did not develop side by side with cysts, but with cancer cysts were conspicuous by their absence. He did not care how the diagnosis was made, but if Dr. MacCarty must have the whole breast for examination, how could the breast be saved? The "take it out" policy would mean the mutilation of every woman with a lump in her breast.

Brain Abscess.—Dr. ALFRED W. ADSON of Rochester, Minn., reviewed the surgical treatment of brain abscess, enumerating the early signs of the disease, and emphasizing the importance of early diagnosis and early operation. The differential diagnosis between brain abscess and associated lesions was discussed and lantern slides presented showing the various possible positions of brain abscesses. In the cases which he had studied in the clinic seventeen were nonoperative and nine operative. Of the seventeen, three cases were non-certified in that one patient died after leaving the clinic, two recovered slowly but with symptoms. Of the nine operated cases four recovered and five died.

Surgical Experience with an Intracranial Approach to Chiasmal Lesions (Lantern Demonstration). Dr. GEORGE J. HEUER of Baltimore, Md., discussed the findings in thirty-seven cases, twenty-four of which had been operated upon by his method of intracranial approach. On six of the twenty-four a second operation was performed. In this series two per cent were hypophyseal and the rest chiasmal lesions. These tumors might grow to considerable size before they gave symptoms, and the direction of the intracranial extension of these tumors might be upward, forward, lateral or posterior. The extent of the lesions might be determined by clinical and roentgen-ray examinations, confirmed by necropsy. In practically every case the tumor was accessible by the intracranial method of exposure. The need of a satisfactory intracranial approach to chiasmal lesions had led him to employ the technique as described by means of lantern slide illustrations.

Dr. DOWMAN of Atlanta, Ga., was pleased to know that Dr. Adson had had such a high percentage of recoveries in brain abscesses; this had not been his experience. He had had no experience with the intracranial route of approach as described by Dr. Heur. Where there had been a large amount of sellar excavation, showing that the tumor had made definite progress downward toward the sphenoid, he had been inclined to do a decompression operation by means of the transsphenoidal route, which he believed to be less dangerous and much easier of accomplishment than the intracranial method. Where there were difinite symptoms in lesions in the neighborhod of the

chiasm the intracranial route was preferable. The high mortality in these cases, attributable to the fact that the reach the surgeon at a very late stage, brought up the question of education in the recognition of this class of cases. The surgeon could do a great deal in the matter of technique, but he could not hope for favorable results when the patients continued to consult him at such a late stage.

Dr. DORRANCE of Philadelphia, basing his observations upon his war experience, called attention to the danger of meningitis and hernia after operating the dura. The technique used in France called for the introduction of a tracar through the dura into the abscess, the insertion of a piece of split tubing or a special variety of rubber tissue, the dilation of the channel, and the introduction of dichloramine-T. With wide exposure the mortality was comparatively low.

Dr. ADSON, in closing the discussion, said in all cases removal had been extensive and he had washed out with normal saline, packing with gauze, except in two cases in which he had inserted a drain. Contamination of the dura by pus was very apt to result in death. The duration of symptoms varied, but the average duration in his cases was six months. Some cases passed through the stage of hypersecretion, entering a stage of hyposecretion. In every such case there was minus metabolism and low pressure; in other words, death occurred in patients who were hypopituitaries at the time. He agreed with Dr. Heur that both the transsphenoidal and the intracranial methods of approach were indicated. The fact that a patient had a pituitary lesion did not mean that that patient must be operated upon. Something should be done for him before operation.

Hemangioma and Lymphangioma: Their Response to the Injection of Boiling Water (Lantern Demonstration.)—Dr. FRANCIS LE S. RIDER of St. Louis, Mo., referred very briefly to the history of this procedure and particularly to the work of Dr. John A. Wyeth of New York. Hemangioma and lymphangioma bore a close relationship to each other clinically, the chief difference being concerned in the difference in the nature of the contents of the vessels or spaces. Each might develop in any part of the body, but the face was a particularly favorable locality. Growth was usually slow, and not associated with pain. The danger to life from these growths depended upon the location and size. Surgical treatment was limited to tumors which were favorably situated, and in which operation could be undertaken without great hemorrhage, loss of important structures, or disfigurement. The technique of injection and types of cases were illustrated by means of lantern slides. The injection of boiling water into a hemiangioma was followed by a mild systemic reaction. Complete disappearance of the tumor had usually resulted in his experience. The injection of boiling water into a lymphangioma was frequently followed by violent systemic disturbances, and the results contrasted negatively with those obtained in hemiangioma. Some benefit was obtained, but complete disappearance of the tumor had resulted in some of his cases. He emphasized the importance of the exercise of caution in the employment of this method in lymphangioma because of the fact that this growth favored greater inflammatory invasion than did hemangioma, and excited more marked systemic disturbances.

Second Day—Thursday, April 29.

Chairman's Address: Military Nerve Surgery.—Dr. DEAN D. LEWIS of Chicago said in this address that absolute repair of peripheral nerves could be secured if surgical principles were observed. The introduction of the silver stain by which neuraxes could be recognized had made it possible to say that the regenerative process took place in the proximal end of the stump, while Wallerian degeneration went on in the distal end. The mechanism of regeneration was described. Certain factors were concerned in the failure of this process of regeneration. The first of these was the formation of scar tissue; the second was failure to take into consideration the internal topography of the nerve; the third was the length of time which had elapsed between the receipt of the injury and the attempt at nerve repair. Cases in which the most satisfactory repair was obtained were those operated upon within from three to three and one-half months after the injury. Up to the ninth month the results were fairly satisfactory; after that there was a distinct falling off of results. Primary nerve suture was the most important thing; the type of suture did not make much difference, so long as it insured closure of the epineurium. The technique of primary end-to-end suture was described. Many methods had been suggested for the prevention of scar-tissue formation after suture. The best way was to make the dissection along the intermuscular septum, burying the suture between the septa. Where there was a defect, tubulization was necessary. Out of 135 cases of nerve suture it had been necessary to tubulize in only five. By the exercise of greater care it might have been possible to use an end-to-end suture in these. Autotransplantation had been resorted to in some cases. One observer had found no return of motor function after a year to eighteen months. The speaker had examined clinically some cases in which autotransplantation had been done and had found a definite Tinel sign in some. In those cases of autotransplantation in which there was evidence of increase in the transplant, if the Tinel sign was present re-exploraton should be done, resection made and end-to-end suture employed. Neurolysis had been done in another group of cases. There was a good deal of difference of opinion as to the value of neurolysis. In the first place there was a tendency for peripheral nerves to recover spontaneously. Out of six hundred wounded three had recovered spontaneously and rapidly. In physiological interruption of nerve function without anatomical division neurolysis was important. There was a definite time relation in which neurolysis should be performed. Performed late, it gave a low percentage of recovery. Another group of cases, not often seen in civil life, included causalgia, which was one of the most distressing conditions encountered. It was characterized by a peculiar burning pain in the extremity below the point of injury, constant as a rule, paroxysmal at times, and finally so severe as to give rise to mental changes. The best way to control these cases was by means of the injection into the nerve of sixty per cent. alcohol. Within twenty-four hours the pain would disappear and did not recur. As a rule there was very little motor palsy; when present it generally disappeared within a few weeks. The speaker emphasized the importance of the early exploration of the peripheral nerve after injury. Waiting and making clinical examinations was a loss of time.

Squamous Cell Carcinoma of the Kidney.—Dr. ALEXANDER PRIMROSE of Toronto, Canada, reported a case with a multiplicity of lesions, including malignant growth in the kidney, congenital "horse-shoe" kidney, and calculous pyonephrosis. The study of this condition shed important light upon the etiology of malignant growths of the kidney. Primary carcinoma of the kidney was not of frequent occurrence, particularly if one excluded hypernephroma. Hypernephroma was now supposed to be derived from adrenal rests, while primary cancer originating in kidney tissue was derived from the renal tubules. A study of the literature left no doubt that such tumors arose from the transitional epithelium of the pelvis of the kidney. Two types of cases were seen, first, those of infiltration carcinoma, and second, those of adenocarcinoma. Malignant squamous cell carcinoma of the kidney gave rise to extensive metastases. The presence of stone in the kidney was an etiological factor. Such cases should be treated in a conservative manner. In the presence of septic processes immediate relief of urgent symptoms should be accomplished by the least amount of trauma. When symptoms of acute infection had subsided, more radical measures might be employed.

Dr. ARTHUR DEAN BEVAN of Chicago contrasted the views held twenty-five years ago concerning kidney tumors with those of the present time. Whereas formerly the majority of kidney tumors were considered carcinoma, now it was the view that hypernephroma was the common type and that it originated in adrenal rests. Out of a hundred cases of kidney tumor perhaps eighty would be hypernephroma. Carcinoma was very rare. He had had only four cases in which the microscope showed definitely carcinoma. It orig-

inated either from the epithelium of the pelvis and the calyces or from the tubules of the kidney as adenocarcinoma. In his limited series the tumors were malignant papilomata of the pelvis of the kidney, such as occurred in the bladder and occasionally in the ureter. Leucoplakia as observed in the bladder, ureter, and pelvis of the kidney developed in the presence of some form of irritation, notably calculus.

Dr. WILLIAM J. MAYO of Rochester, Minn., thought the consideration of the constitution of the kidney would elucidate the question of solid tumors of this organ. He agreed with Dr. Bevan regarding the frequency of hypernephroma, but he did not accept the view that this tumor originated in adrenal rests. The case reported was exceedingly interesting because it occurred in a "horse-shoe" kidney, which added to the difficulties of removal. He had had a number of cases of cancer of the kidney and had found the operation exceedingly difficult. There was always the danger of getting into the duodenum in the course of the operation. He cited two cases in which this accident had occurred. He had since had two similar cases and had known of a number of others in which the duodenum had been accidentally opened. Another accident that might occur in operating on the right side was getting into the vena cava. He had had this happen in two cases. This accident was not as dangerous as might appear, as it was possible to mend the vena cava.

Dr. JOHN J. GILBRIDE of Philadelphia called attention to the difficulties of diagnosis in consequence of the absence, more or less complete, of local signs or symptoms until the disease was well advanced. Even after one was able to palpate a definite mass in the kidney the urinary changes might be little known. In cases of hypernephroma or sarcoma there might be absence of blood in the urine until the patient was suffering from uremic coma or died. Elevation of temperature and increase in pulse rate might be noted, giving rise to the suggestion of infection. Even after extensive study and careful *x*-ray examination the diagnosis of infection might be made. These were possibilities to be borne in mind.

Dr. ALBERT J. OCHSNER of Chicago called attention to the physiological reasons for the rarity of squamous cell carcinoma of the kidney. Three conditions helped to cause the production of carcinoma: first, irritation, as from the presence of stone in the kidney; second, stasis; third, acid medium, present all the time. So long as the urine was normal, even in the presence of uric acid or oxalate of calcium stones, the irritation was slight because of the constant washing away; but in the presence of stasis the irritation was sufficient to give rise to cancer.

Congenital Hypertrophic Pyloric Stenosis in Infants: Review of 175 Cases in Which the Fredet-Rammstedt Operation was Performed.—Dr. WILLIAM A. DOWNES of New York City presented this series, which included every case operated on by the Fredet-Rammstedt method from May, 1914, to January, 1920. There were 145 recoveries and 30 deaths, giving a mortality of 17.1 per cent. All cases of death in the hospital following operation were classed as operative deaths, although several had resulted from gastroenteritis, from two to four weeks after operation. The majority of the patients discharged as cured had been followed to the present time, and in no cases had there been return of symptoms. Two patients had died of pulmonary conditions one and one-half years after discharge. In these cases necropsy revealed that the pyloric tumor had entirely disappeared. The diagnosis in these cases was made from the physical findings. Vomiting was the first symptom, the onset dating from this occurrence. Upon inspection of the abdomen visible peristaltic waves passing from left to right might be noted in nearly every case. This was of great value as a diagnostic sign. The tumor might be found. Just before palpating the abdomen the stomach should be emptied, after which the hard, movable nodule at the pyloric end of the stomach might be found in nearly every case. A few whiffs of ether might be given. Once this nodule was distinctly felt its recognition would be easier afterward. It was extremely important to develop the ability to feel the tumor, as this diagnosis had been proved correct in over ninety-nine per cent. of the cases. It had not seemed wise to wait for an *x*-ray to be taken, as immediate operation had seemed to offer the only means of saving life in these cases. The history and the physical signs established the diagnosis. Medical treatment was justified provided the baby did not lose more than twenty per cent. of body weight during this time. If there was no improvement, or if the patient was better one day and worse the next, it should be considered in the severe group, and immediate operation should be recommended. Objections to surgical treatment no longer held, in view of the perfection of technique.

Dr. DEAN D. LEWIS of Chicago had performed twelve gastroenterostomies, with three deaths. All had rather a stormy time. He now considered the Fredet-Rammstedt operation the simplest and best for the purpose, and intended to employ it hereafter. He had operated in two cases in which the diagnosis of plyoric stenosis had been made, in which there was projectile vomiting and in which the tumor was supposed to be present, but upon operation no tumor was found.

Dr. HILL of St. Louis, Mo., had found five cases of pyloric stenosis in one thousand children born in a foundling hospital. It developed in about one case in two hundred. From the increasing number that came for operation it would seem that the condition had been overlooked in the past and that physicians were just beginning to recognize it. When patients were operated upon early they were in fair condition and the results were good, but when the patients were brought in practically dead, as was too often the case, of course the results of operation were not so favorable He had performed the Rammstedt or Fredet-Rammstedt operation in twenty-two cases, with twenty-one recoveries and one death. In the case that died there was suppression of urine twenty-four hours before the patient was admitted to the hospital, convulsions had occurred before admission, and the temperature was 103° F. The patient died of uremia. He had to reopen the abdomen in two cases, in one of which this was due to not making the opening large enough at the first operation. He made a second incision alongside the first. The child recovered. In the other case artificial respiration had to be resorted to. In six cases the wound broke open and had to be resutured.

Dr. STRAUSS of Chicago thought there was a distinct field in the surgery of children and infants. He had seen, since 1914, 163 cases of congenital pyloric stenosis with three deaths. Of this number 160 were treated surgically, the remaining three, medically. He insisted upon fluoroscopic examination because contractions under the fluoroscope were absolutely pathognomic. It also gave indications as to whether the case should be operated upon or treated medically. The speaker emphasized the technical point of shelling out the mucosa instead of infolding it. When this was done there was not one drop of vomiting, and the child could take food immediately after the operation.

Dr. LE WALD of New York City emphasized the frequency of this condition in children, and the importance of *x*-ray diagnosis, which he had brought out in 1912. He had stated at that time that no case in which *x*-ray examination was made would fail to give a diagnosis. Of all the gastrointestinal examinations which he had made in the last ten years he knew of no condition in which the diagnosis was so definite as in congenital pyloric stenosis. The diagnosis had been made in one hundred per cent. of these cases. The differential diagnosis between cases which might recover under medical treatment and those which should be treated surgically could be made with accuracy. The findings, whether fluoroscopic or plate, made little difference to the surgeon, but if the case was under medical care and one wished to convince the medical attendant and perhaps the family of the seriousness of the diagnosis and the necessity of surgical intervention, we knew of no better way of accomplishing this than by demonstrating the lack of passage of food through the pylorus up to four hours.

Dr. ARTHUR DEAN BEVAN of Chicago had been strongly impressed with the importance of operating in these cases under local anesthesia. It was so much

easier and safer that it had revolutionized the Rammstedt operation. There was a great difference between the old operation under general anesthesia and the present-day plan of operating under local anesthesia. On account of the starved condition of these patients there was a tendency to slow wound repair, consequently special care should be taken to get perfect closure, and to cover the wound with adhesive plaster so as to make it impossible for it to open. Special attention should be paid to the after-management of these cases. The adhesive straps should be kept on for twenty days, until wound repair was assured.

Dr. RANSOHOFF of Cincinnati, Ohio, thought the Rammstedt operation made the appeal of complete efficiency and absolute simplicity. All modifications seemed unnecessary. He had had one death from the opening of the duodenum. He asked Dr. Downes to give the exact procedure of the closure of these wounds of the duodenum. He also asked the essayist if he had found enlarged thymus more frequently in cases of congenital pyloric stenosis than in other children.

Dr. DOWNES, in closing the discussion, presented lantern slides to describe the technique as he had employed it. He did not subscribe to the views expressed by Dr. Bevan regarding the use of local anesthesia in these cases. He had tried it in various cases without very satisfactory results. It was important not to allow the stomach to extrude and not to let the intestine come out into the wound, and with a child struggling and crying, as it would with local anesthesia, he did not see how this could be prevented. He always used ether, never chloroform. He could make no statement regarding the frequency of enlarged thymus in these cases.

Dr. BEVAN added that he had operated upon between fifteen and eighteen hundred cases under local anesthesia and the infants did not struggle at all. Occasionally the child vomited, but this might happen no matter how well the anesthetic was given.

Ulcer of the Jejunum Following Gastroenterostomy.—Dr. WALLACE I. TERRY of San Francisco, Calif., had carried out various experiments, during the winter of 1901, with the idea in mind that gastric juice was responsible for these ulcers, but his premise had not been established. Non-absorbable sutures had been suggested as the almost exclusive cause. His own opinion was that the principal factor was the introduction of non-neutralized acid gastric juice, and that trauma further lowered the resistance of the jejunum. Whether infection played a part was a question. Two types of ulcer had been recognized, marginal and jejunal. Three cases were cited. Pain and tenderness referred to the left of the umbilicus were the striking symptoms in these cases and in others found in the literature. The pain might be referred. From his investigations he concluded, in part, that the exact etiology of these ulcers was still in doubt; that probably the principal factor was the conversion of acid chyme which had lost its neutralizing quality; that trauma from retained non-absorbable sutures might play a part; that great care should be taken in the use of non-absorbable sutures for purposes of anastomosis; that patients should be instructed with regard to suitable diet for a year; and that the patient should be urged to seek competent advice for abdominal pain.

Dr. J. SHELTON HORSLEY of Richmond, Va., said jejunal ulcer after gastroenterostomy was found in a small but definite number of cases caused by the operation; without this operation it practically never occurred. Trauma and the use of non-absorbable sutures favored its occurrence, but it occurred in the absence of non-absorbable sutures and trauma. There seemed to be something defective in the physiology of the stomach and intestine following this operation. Pyloroplasty would restore the physiology of the stomach in a few months so that by *x*-ray examination it could not be distinguished from a normal stomach.

Dr. WILLIAM J. MAYO of Rochester, Minn., said gastrojejunal ulcer would happen very rarely if one used fine catgut instead of silk or non-absorbable sutures. He was glad to see from a recent article by Moynihan that this had been his experience. Twelve years ago the speaker had reported before the American Surgical Association twelve cases of so-called marginal ulcer. He had never seen a true jejunal ulcer. The ulcers he had seen had been in the suture line. He had seen cases in which the suture line had worked through the abdominal wall and had been removed by means of a toothpick. He emphasized the use of fine catgut for sutures, turning in a fine line of tissue, and being careful about the blood supply. He had seen only three cases of gastrojejunal ulcer in which catgut had been used. The final diagnosis could be made by *x*-ray in over ninety per cent of cases. In a large majority of cases when patients returned after gastroenterostomy complaining of the same symptoms which were present before the operation, the diagnosis of gastrojejunal ulcer might be made.

Dr. ALBERT J. OCHSNER of Chicago thought Dr. Mayo's results did not come from the use of one kind of suture or another, but because he made the gastroenterostomy at the lowest point of the stomach, so that there was no accumulation of acid gastric juice. In all the cases in which the speaker had found jejunal ulcer there was saculation of the stomach.

Dr. STRAUSS of Chicago directed attention to the possibility of infection in these cases, and referred, in this connection, to the work of Rosenow, who had brought out the view that ulcer was a localized infection. Bacterial infection undoubtedly played an important rôle in the breaking down of the tissues and the production of ulcer.

Dr. TERRY, in closing the discussion, agreed with Dr. Horsley with regard to the part played by acid secretion. Pyloroplasty as done by Dr. Mayo restored the acid chyme to the duodenum instead of allowing it to go back into the jejunum. The matter of *x*-ray diagnosis was very important.

Surgery of Cancer of the Large Intestine.—Dr. ARTHUR DEAN BEVAN of Chicago based this paper upon experience with cancer of the colon in his clinic. In the diagnosis of this condition the *x*-ray was the largest single determining factor, and yet it was not infallible. The large intestine from the cecum to the middle of the sigmoid was one of the most favorable locations in the body, from the standpoint of permanent cure of carcinoma by operation at an early stage, when the process was limited to the primary focus. By the proper mobilization of the colon a large block of tissue widely removed from the primary focus could be safely excised. From the rectosigmoid to the anus, the prognosis as to a permanent cure of cancer was less favorable, because the anatomical features prevented the removal of a large block of tissue including the primary focus. Colostomy as a preliminary step was a life-saving measure, and should precede any radical operation in the presence of obstruction. He employed a simplified technique for this in which there was nothing original except that he employed local anesthesia, a single suture and one or two bone buttons about an inch in diameter. By means of lantern slides the speaker illustrated the technique employed in removing carcinoma from the cecum to the rectosigmoid junction, the three-step procedure which had been developed in his clinic, and the technique of operating on carcinoma from the rectosigmoid junction to the anus. An inguinal anus was made for all cases except small carcinomas in the lower rectum; these were best handled with the cautery knife.

Operation for Carcinoma of the Rectum.—Dr. GEORGE W. CRILE of Cleveland, Ohio, reviewed mortality statistics and the results obtained by various individual operators. Investigation and animal experimentation showed that the high mortality of operations for cancer of the rectum was not due principally to shock, hemorrhage or peritonitis, but to absorption of the toxins of feces and of the infected wound. On these premises, an operative synthesis had been established and applied in thirty-two consecutive operations without a death. The operation included primary colostomy under anoci-association, the incision being sufficiently large to permit of ascertaining the extent of hepatic, lymphatic and local involvement. The colostomy was sharply angulated by the insertion of a flanged short glass tube under the loop of colon and on the surface of the skin, thus diverting the fecal stream so that none passed through the rectum. In about a week or ten days, or when the general and local conditions were satisfactory, the major operation was performed in the usual way. Between the colostomy

operation and the major procedure, and for a time after the major operation, the dietetic and hygienic regimen of tuberculosis was followed. Since he had begun to consider the patient as a whole, planning the operation in the way which best conserved the patient, he had seen an immense improvement in the immediate results, greater oportunity was afforded for making a wider resection, and the operability of these cases was increased.

Dr. DANIEL F. JONES of Boston, Mass., opened the discussion on the papers of Dr. Bevan and Dr. Crile. He assigned two reasons for the improvement in the statistics of cancer of the large intestine, first, the immobilization of the colon, and second, the giving of a safety-valve by colostomy or cecostomy. However, due credit should be given to the general practitioner for his part in this improvement, for the good results were obtained in cases that were operated on early, and not because of any particular technique employed. The importance of educating the general practitioner in the early diagnosis of cancer could not be emphasized too strongly. He could not be expected to make a diagnosis of carcinoma of the colon, but he could be educated to recognize the symptoms suggestive of this condition and to send the patient to one who could make the diagnosis and operate early. The surgeon and not the general practitioner should decide the question of the operability of these cases. Referring to Dr. Crile's paper, the speaker said statistics were of no value unless one knew the percentage of cases seen by the man who operated upon the given patients. The value of preliminary colostomy was very great.

Dr. WILLIAM J. MAYO of Rochester, Minn., had learned much from these papers as to how the high mortality in these cases could be materially reduced. The points in technique given by Dr. Bevan and the suggestions regarding the after-care of the patient given by Dr. Crile were all valuable. The question of operability brought out by Dr. Jones was also important. In the majority of instances the patients sent into the large hospitals for operation were not sent in by men of large experience, but by those of lesser experience, and as a consequence, in a large percentage of the cases the patients were sent home as hopeless. That was true in the ordinary form of dispensary examination. In their earlier work they had a low mortality and a high percentage of cures, but seventy-five per cent. of the cases were sent home as hopeless, and only thirteen out of a hundred were alive at the end of five years. When they operated on seventy per cent. they had twenty-five per cent. alive at the end of five years instead of thirteen.

The discussion was continued, by invitation, by Colonel Waring of London, England, Dr. Demarest of Paris, France, and Captain Voncken of Liége, Belgium.

Dr. CRILE, in closing the discussion, said that inasmuch as he did not go into the technique he might have left the impression that the colostomy was permanent, which was not the case. He emphasized the importance of cutting off the fecal streams at a certain situation. End-to-end anastomosis could be secured and then the temporary colostomy could be dropped back. So far as statistics were concerned, nobody could make a satisfactory series of statistics. The series would not run even for various reasons.

Roentgenologic Experience with Pneumoperitoneum. (Lantern Demonstration.)—Dr. ARTHUR STEIN and Dr. WILLIAM H. STEWART of New York City, made the observations detailed in this paper, which was read by Dr. Stewart. The findings were based on one year's practical experience in a series of nearly eighty cases in which there had been no untoward effects following oxygen inflation of the peritoneal cavity (pneumoperitoneum) for purposes of roentgen ray examination of the abdominal organs. They considered the information gained a distinct advance. The method should be reserved for cases which could not be cleared up by ordinary diagnostic procedures. It was a strictly surgical procedure; the needle should be introduced only by one who had had surgical experience. A lumbar puncture needle was used, attached to a sterilized rubber tube connected directly with the oxygen tank. The oxygen was allowed to flow gently into the abdominal cavity until sufficient distention was caused to displace solid organs. Two to four liters would be sufficient. If the nurse by chance should turn the oxygen on too fast the rubber tube would slip off the lumbar puncture needle and no harm would be done. The posture that gave the most satisfactory information was with the patient lying on the abdomen. The oxygen separated the organs more satisfactory than with the patient in any other position. Deflation or withdrawal of the injected oxygen from the abdominal cavity after the roentgen picture was obtained had become a routine procedure to guard against subjective discomfort. This was necessary in order to render the method painless. The method yielded startling revelations and promised a wide extension of the diagnostic scope of the roentgen ray in general abdominal surgery as well as internal medicine. For the differential diagnosis of tumors of the liver and spleen, for the diagnosis of atrophic cirrhosis of the liver, pathological conditions of the gall bladder, and many other abdominal conditions, the method was a useful addition to the diagnostic equipment. The method and apparatus employed by the essayists were described by means of lantern slides.

Dr. GEORGE E. PFAHLER of Philadelphia thought the method had increased the usefulness of the *x*-ray to a considerable extent. One should keep in mind, however, the ordinary method before depending upon this. In practically all instances it was possible to demonstrate the liver and the spleen by means of the ordinary fluoroscopic or plate method. The method was of distinct advantage in demonstrating irregularities on the lower border of the liver or on the right border of the spleen, in distinguishing dense shadows found in the lower part of the chest from the solid tissues in the abdomen or the liver or the spleen, and in outlining enlarged glands or adhesions in the chest. From a technical standpoint the speaker asked Dr. Stewart what he did with the needles during the time that the patient was lying on the abdomen.

Dr. ORENDORFF of Philadelphia had injected oxygen more than four hundred times. Some patients had received it as many as ten times, and many from five to eight times. He was using it as a therapeutic agent in cases of peritoneal adhesions.

Dr. STEWART, in closing the discussion, reiterated that the method described should never be used except where the information could not be obtained by the ordinary means. Answering Dr. Pfahler's question regarding the needle, he said the needle was not kept in place, but was reinserted for purposes of deflation. The simplicity of the apparatus was important. He had eight cases without a rise of temperature and without a fatality.

Ether-Oil Colonic Anesthesia.—Dr. WALTER LATHROP of Hazleton, Pa., spoke from the standpoint of the operating surgeon, basing his remarks upon an experience of nearly a thousand cases of various kinds, chiefly goiter. The experimental work of Gwathmey, Baskerville and Wallace, to determine the rate of evaporation of ether from oils, and the tests made by them with vegetable, animal and mineral oils, had demonstrated, among other points, that while ether boiled at 36.6 degrees C., it did not escape violently from an oil-ether mixture, as from an aqueous mixture when heated to a higher degree, nearly to 37 degrees C., or body temperature, and that the rate of separation of ether from oil quickly acquired a definite and fairly fixed speed. This rate of separation was important, as a proper content of ether might be maintained in the blood to produce a desired effect, as for example, the surgical stage of anesthesia. Four factors, acting in harmony, helped to maintain an even anesthesia: 1. The constant rate of evaporation of the ether from the oil. 2. The distention of the colon, causing less ether to be absorbed than when partially distended. 3. As the ether left the oil both mixture and gut were cooled, and this retarded elimination and absorption. 4. The difference between the absorptive power of the colon and the eliminative capacity of the lungs. Within five minutes after the injection of the mixture into the rectum it was heated to body temperature. Some of the ether left the oil in the form of gas, which was absorbed by the blood in the capillaries about the colon. The ether was carried through the liver by the greater circulation to the heart, and from there it was pumped into the lungs, where some of it was excreted by the

air passages, while the remainder was re-absorbed and carried on to the brain and central nervous system. The odor of ether and paraldehyde could be detected on the breath in from three to five minutes after the administration of the preliminary dose. The accumulation of mucus or saliva, seen often in inhalation anesthesia, was absent; there appeared to be no irritation of the lungs, as only the ether required for narcosis passed through the respiratory tract, and the bronchial secretions which were increased by local irritation under inhalation methods were absent. The respiration was normal as a rule, and very seldom noisy or stertorous, if the anesthetist watched the patient. The eye reflex was usually retained, even though good muscular relaxation was present. The pulse maintained an even plane, in ordinary cases remaining full and strong, if the pulse was already rapid, as in hyperthyroidism, it usually remained so. The blood pressure varied. In cases of great nervous tension, as in exophthalmia, observation had shown that the blood pressure fell after the patient was asleep, usually rising immediately on the regaining of consciousness. The diastolic pressure was usually low. After oil-ether colonic anesthesia there was less vomiting or nausea, the patient was usually comfortable, and could retain nourishment. Of great importance was the fact that there was considerable analgesia for some time, often two or three hours, which added to the ease of the patient. Anoci-association, as carried out by Crile, could be employed with this method, and no doubt was very valuable in many conditions, especially exophthalmia and hyperthyroidism. Ether-oil anesthesia was especially useful in head and neck operations, where the operator was not troubled by either the cone or the anesthetist. In hernia, especially as seen in patients with asthma, the patients slept calmly throughout, with none of the choking and cyanosis seen under ether by inhalation. Patients with short thick necks were especially good subjects for colonic anesthesia. The most valuable of all its uses was in conditions of high nervous tension. In the matter of technique of administration, it was important that the method be employed by one having experience. The patient should be under observation for twenty-four hours or more. The evening before the operation an enema of soap suds (two pints) was given. A second enema of one or two pints of clear tepid water was given early the next morning. If, for example, the operation were scheduled for 11 A. M. at 9.30 two drams of olive oil (warm), three drams paraldehyde, and four drams of ether were given, the patient being kept as quiet as possible. At 9.50 morphine, gr. ¼, and atropine, gr. 1/150, were administered hypodermically. At 10.20 ether, three or four ounces, olive oil (warm), two ounces, were given. The oil and ether were first put in a bottle and thoroughly shaken. The patient should be on the left side, with both knees flexed, the right acutely so. A rectal or colon tube was used with a funnel, and inserted not over six inches, care being taken to have the mixture in the tube and all air expelled before inserting the tube. The mouth and nose were covered with several thicknesses of gauze. The injection was given slowly, about one ounce per minute, the funnel being held about three inches above the level of the patient. The tube was clamped and allowed to remain in the rectum so that the mixture might be withdrawn during operation should there be any indication for doing so. If the patient showed any excitement, fifteen or twenty drops of chloroform would usually overcome this. If the patient could not retain the oil and ether mixture, the attempt to administer it should be abandoned. The patient should be ready for operation in from twenty to thirty minutes from the time of the last injection. The reversed Trendelenburg position seemed to aid in maintaining an even plane of anesthesia. The jaw should be supported to prevent obstruction of respiration. After completion of the operation the bowel should be well irrigated with tepid water until it returned clear. The colon might be gently massaged from right to left to aid this. One pint of water was then introduced into the bowel and left, or olive oil might be given (four ounces) to prevent irritation. Ether-in-oil colonic anesthesia was contraindicated in rectal diseases or where pain was caused by its administration.

Dr. JAMES T. GWATHMEY of New York stated categorically the fundamental principles which had been demonstrated in the evolution of colonic anesthesia: (1) It was one of the easiest methods to administer, requiring only a rectal tube with funnel attached and quiet surroundings for the patient. (2) It was one of the safest methods, the margin between full surgical anesthesia and a toxic dose being greater than with any other method. (3) It was one of the most pleasant methods for the patient, as attested by the fact that those who had tried other methods preferred the colonic. (4) It resulted in a greater relaxation of the musculature than was usual with any inhalation anesthetic. (5) It required a smaller amount of ether per hour than any other method of administering ether, the estimated amount being two ounces per hour, which seldom varied. (6) It was regulated as easily as any inhalation method; by covering the face with a towel to deepen the anesthesia, by placing an airway tube to lighten, or by unclamping the rectal tube and draining the residue and flushing thoroughly, it could be terminated at any time so far as the anesthetic was concerned, the patient continuing to sleep from the other drugs used. (7) The brain was more completely protected against reflex stimuli than by any other method of inhalation anesthesia, as proved by the fact that the patient at times changed his position or conversed with the surgeon, as in spinal analgesia. This was to be differentiated from the so-called analgesia, but really amnesia, with nitrous oxide and oxygen. (8) The complete analgesia and anesthesia of the colonic method was dependent upon the synergistic action of all the drugs concurrently given with the ether. An extra amount of ether would not have the same effect. (9) The quiet sleep and analgesic stage for a few hours after the anesthetic was terminated was an advantage to the patient. (10) While the rate of absorption was slightly different with each patient, dependent upon the age, temperature, and general condition, it was constant. An anesthesia deep at one time and light at another was physiologically impossible. The tendency to light or deep anesthesia was recognizable within fifteen minutes after administration, and was easily regulated in the manner described.

Dr. ALEXANDER PRIMROSE of Toronto, Canada, corroborated Dr. Lathrop's experience. Rectal anesthesia afforded the greatest possible comfort to the operator in cases in which it was indicated. He had employed it in a large series of cases with gratifying results.

Dr. J. SHELTON HORSLEY of Richmond, Va., had found the method disappointing in exophthalmic goiter cases, probably because of the impaired eliminative power of the liver and kidneys caused by the disease.

Dr. GEORGE W. CRILE of Cleveland, Ohio, said the removal of the psychic factor was important.

Miscellany.

Death of Dr. Hernandez of Venezuela.—Doctor José Gregorio Hernandez was born in Libertad, Province of Trujillo, Venezuela, in 1864, and at the age of 14 entered the Colegio Villegas, in Caracas, graduating with the degree of Bachelor of Philosophy in 1882. He attended the Central College of Medicine and took his medical degree in 1888. He studied abroad during the next three or four years, in Paris, London, and Berne, specializing in physiology, histology, and bacteriology. In 1892, after his return, he was placed at the head of the department of experimental medicine in his alma mater, where he remained without intermission for twenty-seven years, up to the time of his death, save when abroad for study. He once made a special trip to Madrid to study histology with Ramon y Cajal. He was very devout and wavered at times between theology and medicine, making several journeys to Rome, and at one time actually beginning the study of theology there. Medicine for him was founded on physiology and this in turn on physics, chemistry, and mathematics. Perhaps as an expression of his sacerdotal bent he never married, saying whimsically that he was wedded to that "pagan lady Minerva." His biographer, Dr. Ovalles, places him in the class with Newton and Kant, as one so absorbed in science as to have no room for domestic life. Hernandez had traveled extensively in North America. On the whole he is best likened to some of the medieval friars, who, sheltered in the cloister, pursued their scientific studies undisturbed. Like Professor Curie he met his death by being struck down by a vehicle—in his case an automobile.—*Anales de la Direccion de la Sanidad Nacional.*

Postabortive Tetanus.—Lapauze, a student at the University of Bordeaux, has devoted his graduation thesis to the publication of sixteen new cases of this accident, four of which he personally beheld. The condition is notably rare and almost always follows criminal abortion. The incubation period is about nine days, and the evolution agrees with that of external wound tetanus. But one victim survived, which is rather a surprise, as post-abortive tetanus counts as 100 per cent. mortal. For this reason the author would always inject serum in every case of criminal abortion as prophylactic, for this is all that can be done to save life. He would flood the cavum uteri with serum and inject it into the spine, as well, if the disease develops. The particulars of the surviving case are not stated, so that credit for any special resource cannot be awarded.—*Revue Française de Gynécologie et d'Obstétrique.*

Differential Diagnosis of Rabies. — Porak contributes a synthetic review of the literature of rabies to the *Gazette des hôpitaux* for January 10, 1920, xciii, 4, from which the following on differential diagnosis may be cited. The phenomena of hydrophobia may be simulated unconsciously in a bitten subject who believes the dog to have been rabid, although such cases are extremely rare; for evidently in psychogenic simulation nature is not closely followed and the behavior of these obsessed subjects does not usually closely resemble the symptom complex of rabies.

An authentic case reported by Barbantini exhibited all the clinical phenomena of the disease, but these subsided at once when the dog, which was supposed to have died of the disease, reappeared in his normal condition and began to caress his master. Another case was reported by Raymond, in which a veterinary seemingly recovered from true hydrophobia when it was shown that a mistake had been made in affirming that the dog which had bitten him was mad. The offending dog had been confused with another animal. In these cases the symptoms come on much sooner than they normally should.

The patients are not to be confounded with subjects of hysterical hydrophobia, for in the latter there need not be any definite history of a bite by an animal supposed to be rabid. Certain hystericals have as a part symptom of their condition inability to swallow water and even the thought of swallowing may cause the same reaction. Of organic diseases tetanus and hydrophobia have often been confused and in not a few other acute infectious maladies inability to swallow has led to confusion, this including poisoning with the *Solanaceæ*, in which the dryness of the throat may make swallowing impossible. Delirium tremens may simulate hydrophobia so utterly that, according to Babes, rabies in a drunkard would probably be masked as delirium tremens. Acute ascending myelites, especially Landry's paralysis, closely simulate the paralytic form of rabies. If a subject who developed tuberculous meningitis should have been bitten by a rabid dog, the similarity of the symptoms in the two diseases would probably create no little confusion between that affection and hydrophobia.

Alcohol in the Cerebrospinal Fluid.—The first observation concerning the presence of ingested alcohol in the cerebrospinal fluid was reported by Sabrazes in 1905. After that period Carrara of Turin studied the subject, making a report in 1913, and Lenoble and Daniel have since taken it up and have made a series of reports thereon, the latest in October, 1919. The points determined were the amount of alcohol ingested, the duration of elimination—which should average ten days, the reactions and technique used, etc. It was learned that if 325 gm. of absolute alcohol is swallowed the drug will enter the cerebrospinal fluid in a concentration of 0.02 per 1000. If the amount ingested is 350 gm. the figure is 3 c.c. instead of 2. If 400 gm. is swallowed, the figure will be 4 c.c., while for 450 gm. it will be 6. The alcohol enters the urine more rapidly, but also leaves it rapidly. The composition and cell count of the fluid are not affected. The forensic importance of the presence and degree of ethylism is self-evident. In addition there is a marked clinical significance, for the discovery of alcohol in the cord will throw light on a number of conditions, as comas, cerebral hemorrhages, meningitis, etc. Alcoholism can simulate numerous conditions which this research may expose. The tests used give the same reaction for alcohol and acetone, hence the latter must be excluded. It is possible that chloral and other drugs may cause further confusion. The method used is that of Grehant and Nicloux, in which potassium bichromate and sulphuric acid are the reagents.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux.*

ON THE CURE OF CANCER.*

BY L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

SENIOR PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

SURGEONS seem to have given up making statements in regard to the cure of cancer. Operations are reported as successful soon after they are performed, but there are relatively few reliable statistics in regard to the ultimate cure of the disease. Some years ago the lapse of two or three years after the removal of a cancer surgically was counted as a cure, but the error of this was soon learned and five years was regarded as the proper time, while some surgeons have been frank enough to say that no date can be fixed when the patient is free from danger of a relapse. But those of us who have had the opportunity of watching many patients see large numbers of recurrences even within the first year, many within three or five years, and others again ten or even fifteen years after operation.

The explanation of the recurrence of cancer is commonly stated to be, that there has been some portion of the diseased tissue left, which has proliferated into new lesions, or that there had already been transference of cancerous elements to lymphatics, blood vessels, or other structures which had continued the disease. Of this no absolute proof has ever been given. It is only observed that recurrences continually do present themselves in or near the scar following removal, and sooner or later other portions of the body are attacked, until gradually a more or less generalized carcinosis develops, which ends in death, in a large proportion of cases.

The real reason why recurrences are so common is that nothing is generally done to arrest or alter the cause which first induced normal cells to take on and continue the abnormal and destructive action which results in the lesion which we call cancer. The only thing that surgery does is to attempt to remove mechanically some portion or all of the diseased tissues which has already been formed, the *product of the disease*, without attempting to change the conditions of the system which led to its production. As well might one excise a syphilitic gumma, or a tuberculous lesion, or a gouty toe, and expect final success.

One hundred years ago the great surgeon, Abernethy, wrote "There can be no subject which I think more likely to interest the mind of the surgeon than that of an endeavor to amend and alter the state of a cancerous constitution. The best timed and best conducted operation brings with it nothing but disgrace, if the diseased propensities of the constitution are active and powerful. It is after an operation that, in my opinion we are most particularly incited to regulate the constitution, lest the disease should be revived or renewed by its disturbance." He then goes on to indorse Lambe's dietetic treatment, giving reasons why it should be fairly tried.

If proper dietary and medical treatment are valuable after an operation they are eminently desirable at the very first suspicion or recognition of a malignant tumor, when they can commonly check its progress or remove it entirely, as I shall hope to show presently. In former writings* I have quoted from a large number of eminent physicians and surgeons who, during the last hundred years to the present time, including Dr. W. J. Mayo, have incidentally referred in the strongest language to the definite or probable existence of some constitutional disorder which has rendered futile their efforts to control the disease.

When we recall that under surgical care the deaths from cancer have risen about 30 per cent. since 1900, while under medical care the deaths from tuberculosis have fallen about 30 per cent, in the same length of time, as shown by the United States Mortality Tables, is there not good reason to feel that a mistake has been made in the understanding and treatment of cancer? When we also consider that there are at the present time in the United States from 250,000 to 300,000 cases of cancer, with new ones constantly developing, and that there were about 90,000 deaths from the disease here during the past year, we should seriously reflect, and examine the evidence which has been repeatedly presented in regard to the constitutional nature of the disease and its relief by means other than surgical. The *x*-ray and radium have undoubtedly been of value in removing some of the local lesions included under cancer, but no one can rightly presume to claim that they can permanently effect a change in the basic or underlying causes of the disease, and no reliable statistics are available as to their permanent cure of true cancer; they do little more than the knife though in a different way. Most of the arguments for surgery, and the pictures shown, relate to cutaneous epithelioma, which can be satisfactorily cured by even simpler means.

*Address before the Tioga (N. Y.) County Medical Society, September 2, 1919.

*Bulkley: Cancer, Its Cause and Treatment. Vols. I and II, P. Hoeber, New York; The Medical Treatment of Cancer. F. A. Davis & Co., Philadelphia.

and with less disfigurement, when not too far advanced.

In our present study on the cure of cancer, ordinary cutaneous epithelioma, as it is really a local affair, is excluded, and reference is made only to true cancer, a constitutional disease, as it affects the breast and internal organs, which latter is not often cured by the knife, *x*-ray or radium.

The question arises, can cancer be cured? Long study and observation, together with the many illustrative cases which I have reported from time to time in the journals and in the volumes referred to, have convinced me assuredly that this can be affected, if sufficient time, patience, and knowledge are expended along proper lines.

Tuberculosis had an enormous fatality twenty-five years ago, but when medical acumen was properly applied the mortality from tuberculosis began to diminish steadily over 30 per cent, by proper dietetic, hygienic, and medicinal measures; for tuberculin has played but an insignificant part in this gratifying result. There can be no question but that the same can be accomplished for cancer, if like means are faithfully and intelligently employed.

But we all recognize that tuberculosis can be overcome only by the most intelligent and persistent care over a long period of time, and also that a relapse may occur if the patient neglects treatment or stops too soon; or, even if after being discharged cured he or she returns to exactly the same mode of life and habitation the trouble may recur.

The same is true of cancer. If it is due to constitutional causes, as has been repeatedly shown, and these can be removed or radically changed, then the systemic process which has caused certain previously healthy cells to depart from normal and take on a malignant action is reversed, and a normal blood stream causes them to again take on a normal action, or they are disintegrated and removed; just as are the products of inflammation, or even the deposits in adiposis, tuberculosis, syphilis, arthritis deformans, etc. Laboratory studies of the blood in cancer have shown remarkable changes in its various constituents, which steadily return to normal as the disease is overcome by proper treatment, while when neglected these lead to the well known cachexia and death from cancer.

There has been altogether too much loose talk in regard to malignancy. The life and death processes in the body are all one, varying from varying causes. For normal and malignant growth are dissimilar only in their methods and activity of growth.

It may be well to remind you of certain definite facts concerning cancer which have been determined by laboratory research, and are almost universally accepted by physicians and surgeons.

1. Cancer is but a deviation from the normal life and action of certain of the ordinary cells of the body.

2. Cancer is *not* caused by a microorganism or parasite.

3. Cancer is *not* contagious.

4. Cancer is *not* wholly of traumatic origin, although local injury may determine the location of the cancerous process.

5. Cancer is *not* hereditary in any appreciable degree.

6. Cancer is *not* altogether a disease of old age.

7. Cancer does *not* especially belong to or affect any particular sex, race, or class of persons.

8. Occupation has *not* any great influence on the occurrence of cancer.

From the absence of any specific cause of cancer and from the many systemic and constitutional symptoms observed in these patients, as has been repeatedly shown, we must fall back on faulty metabolism, or erroneous tissue metamorphosis, as the basic cause for the aberrant action of certain, once normal, cells which form the heterogeneous growth to which we give the name of cancer.

It would take far too long to detail fully here the laboratory and clinical evidences of the truth of this statement, which have been fully detailed elsewhere, but the briefest mention of some of them may be of service in understanding what shall follow.

1. The *blood* has been shown by the laboratory to exhibit many manifest changes, as already mentioned, which indicate vital alterations in the action of the organs which form blood, and so control the nutrition of the body and its cells. A lowered alkalinity of the blood is most common in cancer patients, early and late.

2. The *urine* as an indicator of the state of the arterial blood stream, from which it is formed, has been shown by many to present abnormalities, which, while not pathognomonic, are of significance. Careful and repeated volumetric analyses of its many constituents show that the total output of urinary solids is greatly deficient, both in patients with very early disease and during its entire course. Many observers have demonstrated grave errors in its nitrogenous and sulphur partition, and indican is a common feature.

3. The *intestinal secretion* is almost invariably deficient, and constipation, even in early cases is so common that the toxins produced by the millions of micro-organisms generated through intestinal stasis and fecal putrefaction must be looked upon as one of the prime elements in the causation of cancer. Sir Arbuthnot Lane has spoken of cancer as one of the terminal results of intestinal stasis.

4. The *saliva*, upon which the proper digestion of the starchy elements of food depends, is almost always found to be acid, instead of alkaline or neutral, as I have verified by hundreds of tests both in private and hospital practice; in the latter I have it tested and recorded a quarter of an hour before and after each meal.

But the clinical and statistical studies afford further convincing proof of the correctness of the position which is being developed.

1. Mention has already been made of the remarkable results which have been obtained in tuberculosis by most careful medical knowledge and attention, as compared with the sad, steady rise in the mortality of cancer attending the constant neglect of the same.

2. Aborigines, living simple lives, largely vegetarians, have been shown by any number of observers, in many lands, to be almost if not entirely free from cancer, while many have also reported the definite increase in the disease, and in its mortality, in proportion to their adoption of the customs and diet of so-called modern civilization.

3. Statistics from many countries show that increase in the consumption of meat, coffee, and alcoholic beverages, appears to be coincident with a very great and proportionately greater augmentation of the mortality from cancer. In England the consumption of meat has doubled during the last fifty years, while the deaths from cancer have increased *fourfold.* The United States consumes one half of the total amount of coffee handled in trade everywhere.

4. Nerve shock and nerve strain have been shown to have a direct influence in the production of cancer, and there can be little doubt but that the enormous strain of modern life is an element of importance in this direction; this occurs both through metabolic disturbance, and by operating directly on living cells which take on an aberrant action. Microscopic study has shown great changes in the centrosomes and chromosomes of cells about to be cancer-genetic.

5. The spontaneous disappearance of cancer, as occasionally reported by competent observers, shows that certain conditions of the system may arise which are antagonistic to malignant growth, which points to the possibility of influencing the system in a manner to accomplish the same results.

Laboratory experience has repeatedly demonstrated the controlling effect of diet on cancer in animals. In one extensive series of experiments 75 per cent of 75 inoculated mice developed tumors, while under normal diet, whereas only 19 per cent of other 75 inoculated mice developed such tumors when under a diet with vegetable proteins; moreover the tumors in the latter were hardly larger in 30 days than those in the former in 10 days.

In regard to the cure of cancer what then are the elements to be considered? Naturally they relate both to the removal of the causes which study and experience have shown to have an influence in its production, and also to the employment of agencies which promote such a return to normal metabolism, as shall overcome the disease. This latter is accomplished by such proper activities of the various portions of the system as shall lead to a correct blood stream, which in turn tends to remove offending elements from the body. Both of these are essential and efficient in the cure of cancer, as long experience has shown; neither are sufficient alone.

In many reviews I have been quoted as regarding meat eating to be the cause of cancer: this is only partially true, as may be judged from what has preceded. The true cause is a metabolic disturbance arising from diverse agencies, prominent among which are errors of diet, especially along the line of meat, coffee, and alcohol, together with faulty living and imperfect action of some of the organs of the body. In one decade in England it was found by the Registrar General that cancer mortality was more than twice as great among well-to-do men having no specific occupation as it was among males in general, the ratio being 96 to 44. It was also shown that cancer was much more prevalent per 100,000 in those parts of cities which were occupied by the well-to-do than in poor sections of the city.

Proper diet is unquestionably of the first importance in the prophylaxis and cure of cancer, without which all other measures are relatively worthless. But proper medication and hygienic elements, over a long period, are also absolutely essential, of which I shall speak later.

In order that the patients in my Medical Clinic for Cancer at the New York Skin and Cancer Hospital should understand and follow out a suitable diet, I prepared a card of instructions some years ago, which I have used in public and private practice ever since, in innumerable cases, and with the best results. This has been printed in large numbers and may be freely obtained from the hospital by personal application or by letter.

This diet is not presented as absolutely perfect, that would be difficult to determine, but I have not had occasion to change it much and have revised it but once. Other similar articles of diet, than those mentioned may undoubtedly be taken, but the card is very serviceable as it stands. It was carefully worked out with the dietitian of the hospital so as to represent 2500 calories a day, with about 140 of vegetable protein, and is planned for a patient of about 150 pounds, not taking much exercise.

Cancer is generally considered so hopeless, and the mind of the laity and of the profession is so set on surgery as the only hope, and latterly on *x*-ray and radium, that it is difficult to induce some to believe that there is any hope from other measures, and they sometime hesitate to enter upon the prolonged course of treatment necessary to effect a cure. But as they experience the improvement in health and the lessening of the local trouble under careful treatment they are quite satisfied that if they keep steadily on an uphill track toward health, they are not likely to go down hill again. Also when they realize the prolonged treatment necessary to overcome tuberculosis they are content to thus avoid the knife, with its unsatisfactory results. Many a patient has afterwards told me that they had suffered more mentally by the continued worry and warnings of friends and surgeons, urging an operation, than they had from the disease or the treatment.

The first element of success in the medical treatment of cancer is for the physician to be so thoroughly convinced of its value that the patient shall also have an absolute confidence in it. This will aid both in carrying out every detail of treatment and in giving a hope of cure, which latter undoubtedly assists in the recovery, even as the common despair of cancer patients unquestionably acts prejudicially on the disease; for Tuke and others have shown incontestably that the mental state has a very great effect upon the body in health and disease.

In regard to the actual medical treatment of cancer it is difficult to speak briefly and correctly,

so varied may be the measures required to meet many conditions, over the long period during which treatment must be carried out. It is understood, of course, that as dietary and other errors which contributed to cause the cancerous growth have probably existed for a long time before the growth has been recognized, so a continuance or recurrence of them may induce a repetition of the disease. It is necessary, therefore, for patients to clearly understand that the maintaining of a proper diet indefinitely is essential, and that correct medication and hygiene must also be continued a great while in order to secure and maintain a correct metabolism and proper tissue metamorphosis.

As laboratory and clinical research have shown many systemic errors in early and late cancer, so the medical treatment must be adjusted to meet and overcome these many errors from time to time. It must be clearly understood that there is no "cure all" for cancer and probably never can be. It is impossible to rationally conceive how any one single remedy or measure could possibly effect such a permanent change in the system as would result in producing and maintaining the perfect blood stream necessary to overcome the cancerous tendency. The history of cancer is strewn with the wrecked hopes of innumerable sufferers who have tried the many "Cancer Cures" often vaunted so loudly both by those within and outside of the medical profession, only to end in disappointment. One serum after another has been tried, with seemingly good results at first, owing largely to psychological factors, only to be discarded after a relatively short course. The reason for these constant failures is of course found in the true nature of the disease itself, as has been already briefly presented.

But there are certain chemicophysiological lines along which experience has shown that much can be done with advantage in the medical treatment of cancer. Some seven years ago Dr. Forbes Ross of London published a work on cancer in which he demonstrated scientifically, and very conclusively, the reason why potassium salts were of such great value in its treatment. It was a great satisfaction to find from one who had long been a cancer surgeon, such a scientific support to the practice which I had followed for thirty or more years, and which I now commend to you.

Both in my private and hospital practice I have long used a certain mixture, as a first treatment, in innumerable cases of early and late cancer. The formula is as follows: ℞ Potassii acetatis ʒi, Tincturæ Nux Vomicæ ʒss, Extract Cascaræ fld. ʒi—ʒiv, Extract Rumicis radicis fld. ad ʒiv. Teaspoonful in 1/3 tumbler of water, half an hour before eating; the amount of cascara is varied according to the amount of constipation existing, so as to secure about two good movements daily. The amount of potassa can also be much increased, to secure better action of the kidneys, or to act more efficiently on the local lesion; Ross gives even very much larger doses of the potassa. I have many patients who have taken this mixture for months with only the best results.

But very many other remedies may be required from time to time. It was mentioned a while ago that the total solids in the urine were very deficient; I have often found them not one-half of the amount which was called for by the body weight of the patient, when by careful treatment it was brought up even to above normal. Sweet spirit of nitre in addition will often greatly aid in this, also caffeine in two grain doses, after two or three of the meals.

As one wearies of this mixture the acetate can be given with the nux in an infusion of quassia after meals, and the constipation can be controlled by a cascarin compound tablet (cascarin, podophyllin, aloin, aa gr. ¼) one or more at bedtime.

Iron is often called for in these cases and some form of phosphorus, both of which are important ingredients of normal blood cells. During some period of a prolonged course of treatment many other remedies, tonic, digestive, or other, may be called for, which it is impossible even to mention in a brief address. I only want to impress on you the value of the particular combination I first mentioned, and second that the very greatest amount of thought, patience, and skill are necessary in order to cure cancer. These patients should be seen and watched often and carefully; once a week is not too often. Frequent volumetric urinary and blood analyses assist very greatly in guiding the patient to health. The total volume of the daily urinary output should also be known and recorded, and tested as to its volumetric acidity, and its specific gravity, to learn if the amount of urinary solids are such as are called for by the body weight of the patient. This latter should also be frequently recorded and the tonic treatment guided thereby. In fat subjects it is desirable to reduce the weight, for it is well recognized that cancer goes badly with them. It may seem superfluous to have dwelt upon these homely details, but as "eternal vigilance is the only price of liberty," so in the medical treatment of cancer eternal vigilance alone can accomplish its cure.

It may now be asked what proof I have to offer that cancer can be cured? I would answer that the occasional reported cases of the spontaneous disappearance of lesions recognized as cancer by competent surgeons, shows that a condition of the system may arise which overcomes the cancerous tendency; this leads us to hope and expect that sufficient care and medical acumen may find measures to accomplish the same result; this has been the case, as evidenced by the many cases I have reported, which were well attested by many physicians and surgeons.

If I am asked for accurate statistics as to the mortality of cases thus treated, I cannot present them, for many patients have been seen only in consultation, and many late and post-operative cases have been referred to me, in hospital and private practice, where the general carcinosis was so great that naturally little could be affected. But even in these latter cases the result of most careful dietary and medical treatment have often been so gratifying as to excite comment. When the patients have been under full and complete treatment for some time there is infinitely less suffering, and they have passed away peacefully, without any hypnotic, as I have repeatedly re-

ported. Indeed my observation and experience have satisfied me that morphine, by deranging the metabolism and checking the secretions, often does more harm than good, and my patients have very seldom required it.

When it is remembered that the ultimate mortality of those once stricken with true cancer is commonly accepted as 90 per cent., I am vividly impressed with the vast difference observed in the hundreds of cases which have been cared for along proper medical lines. In my writings I have reported in full over thirty cases of cancer, from among many others, in which the benefit of a properly regulated medical treatment was startlingly manifest. Some of the earliest, well attested breast cases had been followed, two of them for 13 years, and two of them for 16 years, remaining perfectly well, without operation. Two very severe uterine cases, which had been refused operation by several surgeons, remain well for over three years, with no recurrence. Cases with deep-seated cancer in other localities have also been reported, where the results were most striking.

Undoubtedly the most hope for the cure of cancer lies in its early stages, as the surgeons have so constantly affirmed, for after there have been abundant glandular infiltrations and metastases, it is difficult to overcome the disease, because it is recognized that all these cancerous cells themselves contribute a hormone which is poisonous to the system.

But in the earlier stages of the disease the results of complete medical treatment have been most gratifying. In many cases, even where some already had glandular involvement, where the diagnosis had been made by prominent physicians and surgeons, and even when immediate operation, as the only hope, had been insisted on and in some instances arranged for, I have seen the mass and the adenopathy slowly fade away until nothing remained, the patient in the meantime gaining every way in health and happiness.

Time does not permit of giving any extended histories illustrating what has been said, but brief mention may be made of a few, some of which have been already reported in my books.

CASE I.—Mrs. B. C. E., aged 44, seen first in 1892, had a sharply defined tumor of the right breast, tender on pressure, which she had noticed about four months. A well known, prominent surgeon was consulted, who pronounced it undoubtedly cancer, and urged its instant removal. Within six months, after careful treatment, it had entirely disappeared, and remained so for sixteen years, when she was lost sight of. Another similar case, aged 45, seen in 1894, was also watched sixteen years, the breast remaining perfectly normal, and two others for fourteen years.

CASE II.—Mrs. S. J., aged 33, a hard working woman, with two children, was seen at my medical clinic for cancer, February 28, 1917, for a painful lump in the right breast fully an inch and a half in diameter, with sharp edges and axillary adenopathy. The surgeon on duty confirmed our diagnosis and wanted to operate immediately. Within one year the lump and adenopathy had entirely disappeared, and shortly after a surgeon visiting the clinic was told that she had had a cancer, and examining carefully he decided that it must have been in the *left* breast, as there was there a slight chronic mastitis. On several later occasions four other medical men made the same mistake, and the same thing occurred in a private patient in my office. She has now remained well nearly three years, continuing treatment at the clinic.

A single illustration out of many may be given to show how much benefit can possibly come from medical treatment even in desperate cases, recurring after operation.

CASE III.—Mrs. C. M., aged 39, had a very complete operation at the New York Skin and Cancer Hospital for the removal of a tumor the size of a hen's egg from the right breast, with dissection of enlarged axillary and supraclavicular glands. Within one year she returned with ulceration along the line of incision and multiple cutaneous nodules around it. The right arm was enormously swollen and helpless and the liver enlarged two inches beyond the ribs, with nodular margin. When she left the hospital five months later the ulcer had entirely closed, most of the cutaneous nodules had subsided, the liver retracted within the ribs, and the arm had returned to the size of the other arm by accurate measurement. The case attracted great interest and was watched by other attendants at the hospital.

Three cases of inoperable uterine cancer are worthy of mention.

CASE IV.—Mrs. F. L. A., aged 48, weighing 105 pounds, was first seen on March 21, 1916. About one month before several surgeons had found that she had an inoperable cancer of great extent, and refused to operate, giving the opinion that she would hardly live six months. Microscopic sections examined by two pathologists showed it to be a "rapidly growing malignant epithelioma." The improvement under careful medical treatment was immediate and most remarkable, and on December 6 she weighed 110 pounds. In less than six months after she was first seen the surgeon pathologist who had given the opinion above, examined her and wrote "There are no evidences of any disease remaining which can be detected on examination," and on October 20 he wrote "She appears to be absolutely free from disease." She was watched often, coming in from Bangor, Maine, and to-day I have a letter from her saying she was perfectly well and needed no treatment, three years and a half after being first seen, and after she was given only six months to live.

CASE V.—Mrs. H. F. J., aged 52, seen first August 2, 1916, was quite a similar case of inoperable uterine cancer, with some cauliflower excresence. She made rapid improvement, and on October 20 the same surgeon pathologist reported that she was "free from disease, though the healing is not quite complete." A recent letter tells that she remains well.

Another quite recent case still under treatment is yet more unusual in the history of uterine cancer.

CASE VI.—Mrs. W. G., aged 43, came under my care February 6, 1919. In the fall she had seen four surgeons, two of them well known, who found an enormous uterine cancer, on which they refused to operate. She was told there was nothing to be done, no medical treatment, that she had not six months to live, and must go home and take morphine for her great pain. On January 19 she had explorative laparatomy performed in a New York hospital, when it was found that there was enormous infiltration of adjoining parts, and further operation was declined and the wound closed, and she was given not two months to live.

When first seen she was in a deplorable condition, with very great and offensive vaginal discharge, and could hardly crawl upstairs to my office. She has been seen frequently and the progress of the case has been hardly believable. For two or three months past she has claimed that she was well, with absolutely no pain, sleeping perfectly, and exercising freely. The vaginal douche has come out clean and odorless now for several months. Yesterday she was in my office, coming from her home in Northern New York without fatigue, and seemed as well as any one could be. She remarked that "the last three weeks have been the best ever in my life," over seven months after she had been given

two months to live. On May 11, 1920, she was seen in perfect health.

An interesting case of inoperable cancer of the stomach, so diagnosed by several surgeons, now under treatment, has shown very gratifying gain in many ways.

CASE VII.—Mr. D. F. B., aged 68, emaciated and pale, with yellowish skin, has lost 10 pounds in the last six months, with distress over the epigastric region. On examination there was a solid mass about two inches in diameter in the right gastric region, painful on handling. Under treatment the mass has diminished much in size, there is relatively little pain, he has gained some pounds in weight, and seems quite a different person.

If time permitted I could give cases with cancer in various other localities where the results of treatment have been most satisfying, including the rectum, kidney, bladder, prostate, esophagus, buccal cavity, tongue, lip, etc., but what has been mentioned must suffice to show that careful dietary, medicinal, and hygienic treatment can have a great influence over malignant disease.

I realize that the accounts I have given are somewhat surprising, in view of the course usually run by cancer cases, but I can assure you of the truth of all that has been said, and that the cases have all been diagnosed and observed by other physicians and surgeons during their progress. Naturally these cases have been selected from many others, some of which have not responded so well to treatment for various reasons. Some few cases have yielded to the solicitation of others and have undergone operations, but rarely with my consent. Others have wearied of the diet and restrictions, and have disappeared from view. Some have lived far away and have been seen only once or twice, and were not traced, while many were seen in consultation, and could not be followed. A number of advanced and post-operative cases have died easily under my care, but without morphine, which I have very rarely ordered. The number of deaths of which I am cognizant are relatively few compared with the acknowledged mortality from cancer, a few dozen among the hundreds observed; but undoubtedly there are many more than I know of.

What, then, are the conclusions to be drawn from the material now presented? They may perhaps be briefly stated as follows:

1. Cancer is *not* a fearful something of unknown origin, which attacks one person or another, without reason, as the laity suppose.

2. Cancer is but a deviation from the normal growth of previously healthy body cells, which, for some reason, not yet fully understood, take on an abnormal method of growth, and, having once begun, they continue a wild and destructive career, invading other organs and ultimately causing the death of the patient, unless checked in some manner.

3. Cancer has been studied, perhaps more than any other disease, and millions of money and infinite labor of countless intelligent and faithful workers in laboratories have been expended in endeavoring to determine its real cause, but as yet without any unanimity of opinon thereon.

4. Most of the laboratory work has been done on the microscopic study of the tissues, and experimentation on lower animals, principally rats and mice, as also on the morphology of the blood, but not on its plasma, and with relatively little clinical investigation.

5. No one has yet seen the very beginning of cancer in internal organs, although microscopic studies of cutaneous epithelioma have taught much in regard to the earlier changes in cells about to become cancer-genetic; this relates especially to changes in the centrosomes and chromosomes in the nuclei, which control the nutrition and action of the cells.

6. Claims have been made that cancer is due to certain misplaced epithelial cells, or "embryonic rests" of pre-natal origin, but these are found to be of common occurrence in every one, and no explanation has been offered why some and not all of them take on morbid action, or why this should be delayed until later periods of life.

7. Supported largely by laboratory studies, which have been interpreted as pointing to a purely local origin of cancer, surgeons have striven with increased zeal to cure the disease simply by the extirpation of the diseased mass and surrounding tissues, and as the wounds generally heal well they have in times past claimed that cancer was thereby cured.

8. But the very frequent return of the disease in the same locality or elsewhere in one, two, three, five, ten, to fifteen years, has taught many of them the futility of this hope. Moreover, the steady rise of nearly 30 per cent. in the mortality of cancer, since 1900, with the present acknowledged death rate of 90 per cent. of those once attacked, has convinced many that surgery is a failure in its attempts to cure cancer.

9. During the past hundred years many prominent surgeons and physicians, recognizing that the frequency of relapses indicated that the knife could not extirpate the disease, have remarked casually, in many writings and books, that there must be some underlying cause which induced a recrudescence of the malady, and many have casually suggested that it probably lay in the diet or mode of life of the persons affected. But these occasional remarks seem to have been overlooked or not appreciated by the profession, and certainly not acted upon, for the glamour of surgery appears to have blinded the eyes of the profession and laity, indeed until recently little if any attention has been paid to the medical aspects and treatment of cancer.

10. Careful clinical study of patients with early and late cancer have revealed constantly so many deviations from normal in them, and in their secretions and excretions, pointing to deranged metabolism, that the conclusion seems clear that these are connected with the genesis and continuance of the cellular disturbance which we call cancer. This is confirmed by their disappearance as the disease recedes under proper dietary, hygienic, and medicinal treatment.

11. Statistics and close observation have shown that the existence and mortality of cancer have definitely increased, to an alarming degree, with the rapid increase of so-called modern civilization in all parts of the world. Aborigines, and peoples who live largely on rice or vegetarian products, have been shown to be almost if not entirely free from cancer. But as the same peoples mingle with foreigners and adopt their customs of eating and living, cancer has

surely and steadily increased, often to a very great degree.

12. Statistics again show that cancer has increased coincidently with the increased consumption of animal protein, coffee, and alcohol, together with indolence and luxurious habits in general. Of late years attention has also been called to the effect of salt in the production of cancer, and to the absence of potassium in much of the food as a very important feature.

13. Careful laboratory experiments on animals have demonstrated a remarkable influence of certain foods in inhibiting the growth of inoculated cancer.

14. Long experience has shown that an absolutely vegetarian diet, with the total exclusion of animal protein, has a great influence, in the arrest of cancerous development, and in the removal of lesions already formed.

15. Experience has also shown that proper medication and hygiene, directed to the restoration of a perfect metabolism and of a healthy blood-stream, continued a long enough time, together with a correct diet, can and does remove the disease, by reaching its cause.

We have thus seen that true cancer is not purely a local disease, cured by the knife, caustics, *x*-ray or radium, which only remove the *local product* of a long-existing constitutional error, while the internal cause remains, ever ready to produce new lesions and to ultimately destroy life. How long this constitutional error has existed and has been operative it is impossible to tell.

The lesion of cancer undoubtedly begins in a cell, or in a group of cells, which multiply erroneously and seem to have the power to induce other cells to join them in their rampant and malignant action. Those diseased cells, like all the other cells of the body, produce a hormone, or internal secretion, which in this instance has a poisonous action, as has been proved by laboratory experiments on animals.

As the cancerous process goes on, the already erroneous blood stream, excited as we know by all hormones from healthy cells, is further disturbed by this poisonous hormone, and the blood cells and their hemoglobin are altered, as shown by the laboratory, and a pernicious anemia is produced, resulting in the well-known cachexia of carcinosis; this, if not checked, ends in death. Thus we see that the pathological history of carcinoma is not mysterious, or need not be mysterious, but that it is more or less akin to what we know of the pathology of other diseases.

Have we, then, solved the whole cancer problem? This is not by any means claimed. The medical history and treatment of cancer have only begun. Careful laboratory studies on the plasma of the blood, and also on the secretions and excretions, together with abundant clinical study of the disease in every possible aspect, will no doubt result in yet far greater advance in its treatment. Let us hope and expect that observation and study may advance along these lines until there shall result even a much greater diminution in the morbidity and mortality of cancer than medical acumen and patience have thus far produced in tuberculosis.

39 West Fifty-eighth Street.

THE DIET AND HEALTH;

AMOUNT AND KIND OF FOOD REQUIRED.

By JOHN AULDE, M.D.,

PHILADELPHIA, PA.

"We can live without friends, we can live without books,
But civilized man cannot live without cooks."
—Bulwer Lytton.

A survey of the food problem to be of practical value to the general reader who is lacking in the rudiments of dietetics, should aim to correlate the essential factors which have a direct bearing upon health maintenance. While we cannot all aspire to achieve success or prominence in the culinary art, in view of the universal prevalence of deficiency diseases, it is important that every citizen, both young and old, should have reliable information as a guide in the selection of the dietary.

This knowledge, spread broadcast, is bound to instil in the minds of the intelligent laity the fundamental principles underlying nutrition, so that correct eating will become a habit and the study of domestic science a popular avocation. While the American people are blessed with a superabundance of food, we cannot deny the obvious truth that they are woefully lacking in prevision—like Mrs. Newrich, who turned her pink-lined seal-skin coat inside out when caught in a storm, to prevent the fur from getting wet!

Thus, the average business man, who is particular in regard to his bookkeeping, his stock taking, his cost prices and margins, and his overhead expenses, will be astonished when told that his annual consumption of food material is approximately represented by a truckload of bricks and a wagonload of hay besides a tankfull of water and other liquids with a capacity of five barrels—about one hundred and fifty gallons. It will also create no little surprise when he is told that all these various edibles and fluids have a definite chemical composition so that their intrinsic value may be computed with mathematical precision—to the fraction of a gnat's heel—the bricks to maintain structure and function, the hay to furnish heat and energy, the liquids to distribute nutrient material and mineral salts and carry the vital current to perfect the transcendental metamorphosis known as human life.

Digestion and assimilation, rather occult problems for the general reader, can be so fully explained in non-technical terms that "he who runs may read," and with reasonable care and attention to the guiding principles in selecting the dietary we can make health catching instead of disease. Even a limited knowledge of dietetics will enable the chronic invalid to become optimistic, perhaps quoting Horace Mann, "Human Life! How exhaustless and boundless the theme!"

Included in this program several kindred and no less important topics suggest themselves, such for example, as the employment of water and other liquids, the function of mineral salts, especially as related to so-called deficiency diseases, the role of infections and poisons, the correct dietary for health maintenance, and finally, how

to trace the cause of chronic ailments, all of which should be carefully and conscientiously studied and presented from the modern, scientific viewpoint—concise, exact, compact.

The amount and kind of food required depend upon various factors, such as age, occupation, climate, and season of the year. Thus, during infancy and childhood, milk constitutes the most important item. In adolescence, while milk is frequently discontinued, we have no other food material so well calculated to round out the dietary, to promote physical growth and mental development, and as age advances, the addition of milk to the usual dietary often means the difference between prolonged valetudinarianism and a rugged old age.

It is well known that occupation is a prime factor in creating a demand for food. With rare exceptions, the office and factory employee never eats as much as those engaged in outdoor work, whether light employment or manual labor, like the carpenter, bricklayer, or farmer. But it is a patent fact that sedentary workers do suffer from hunger, simply because the dietary is not properly balanced—the foods selected do not satisfy the normal demands of the system, and there arises a craving for some temporary substitute to supply the deficiency, ice-water and soda water for those who suffer from intestinal indigestion, because of the inability to digest the excessive amount of starchy food eaten, candy and sweets for those who lack certain essentials in the dietary required to promote oxidation, pickles for spinsters who aim to subsist on tea and toast, and others whose normal sense of taste has been demoralized by rich and highly seasoned foods, where alcoholic stimulants are taken for the narcotic effects.

Failure of the army ration system in the late war to supply a "balanced ration" is worthy of mention in this connection. It is only necessary to recall the insistent demand of the men on duty and in the camps for candy and chocolates—to counteract the depressing effects attending the constant supply of an excessive quantity of nitrogenous food. Quoting from Major John R. Murlin, of Washington, D. C., an attaché in the Food Division of the Surgeon-General's office (*Journal of the American Medical Association*, Sept. 21, 1918, p. 950), we find the garrison ration provided a daily issue of 20 ounces of meat and 3.52 ounces of sugar and syrup, together. The mess records give the average daily consumption of meat, 13.67 ounces, sugar and syrup 4.11 ounces, or 17.78 ounces all told, an apportionment notably defective—whether considered from the scientific deductions of physiological chemistry, or the dictates of common sense. The army ration total amounted to 4.24 pounds while the food eaten amounted to 3.41 pounds, and the food utilized by each man per day, based upon an average of 185 messes, amounted to 1.63 pounds, a trifle less than half the food eaten.

Dr. Murlin makes a plea for *readjustment of the garrison ration* on a basis more nearly approaching the requirements of field conditions, admitting, however, that a distinction should be made between the training ration and the actual field ration, as in the other allied armies. "For example," he says, "the British home ration, used in the training camps in England, provides only 3,400 calories, whereas the field and trench ration provides 4,250 calories. The French normal ration, used in training camps, provides 3,300 calories, the strong ration, used in actual campaign, 3,600 calories. The Italian territorial ration, used in the training period, provides 2,500 calories, while the combating rations, used in campaign, provides 3,300 calories. The present garrison ration of the United States Army, if selected as written in the regulations and as used in computing the value of the ration, would provide nearly 4,800 calories."

The caloric value of the food consumed by the mess referred to was 3,664, the consumed cost, 42.17 cents and the waste cost 2.99 cents, but no data are available for calculating the mineral constituents.

Special attention should be directed to the gross weight of the food eaten—assuming the same allowance for an entire year of 365 days at 3.41 pounds per day, the total is rather startling, 1,244.65 pounds! Add to this the weight of the water and other liquids taken, six to eight glasses daily, amounting to three or four pounds, we have a total intake in weight running up to about a ton and a quarter.

In view of these startling statistics, isn't it time the schoolmaster was abroad?

Many years ago the writer received a valuable suggestion from an intelligent and practical gentleman who had had considerable experience as a commissary in the logging camps of Northern Michigan. He said a steward in charge of feeding several hundred men during the winter, who were to be kept at work, with no communication with the outside world, should make it a cardinal principle to spend as much money for sugar and molasses as he did for meat, as in that way only could sickness be prevented, efficiency secured, and a friendly feeling maintained in the gang. With an excessive meat diet, he said there was always much sickness, constant "soldiering," even sabotage, with no end of fights on the least provocation.

It is not necessary to emphasize the need for a modification of the dietary incident to climatic and seasonal changes, except to criticize the attempt, in the temperate zone, to combine certain tropical and subtropical features with the usual or ordinary dietary, such as fruit before breakfast.

Reliable data are now available relating to the value of different food materials as a result of extended laboratory investigations. In some instances, animals have been submitted to a restricted diet for the purpose of determining whether the particular food selected would produce the disease from which humans suffered when subsisting upon this special or limited dietary, or with a view to determine what, if any, injurious effects are likely or liable to result, say, from a diet limited to one particular food, or a combination of two or more. Observations on animals, of course, cannot deal with the mental make-up, but valuable data can be collected regarding physical growth, health maintenance, and

reproduction, in all of which the human family is intensely interested.

One of the early tests of this nature (1897), was an attempt to cause the appearance of beriberi, multiple neuritis, by an exclusive diet of polished rice, fowls being selected. When the birds had reached the stage of dissolution a watery extract of the polishings quickly restored them to normal. Since then, laboratory studies have demonstrated that the curative effects of the rice-polishings are due to the presence of what is termed an "accessory food" factor, which is soluble in water, but as yet not isolated (unidentified).

Another interesting experiment (1909) consisted in extracting bread and milk with ether and alcohol, using the residue as a food substance, but it was utterly lacking in nutrition—the animals died from starvation. In the belief that the deficiency was due to a lack of fats (lipoids) in the diet, fats were added, but without appreciable benefit, although when the extracted material was returned to the denatured milk and bread, recovery was prompt. Later studies have shown that milk also contains, in addition to the mineral constituents, potassium, sodium, calcium, phosphorus, and chlorine, an unidentified accessory food factor, which is soluble in fats—and milk as well as certain other animal foods, along with the vegetable foods containing the water soluble substance found in plants, are now referred to as "protective foods."

We are indebted to E. V. McCollum, Ph.D., now of Johns Hopkins University, for his report on extended series of experiments (*Journal of A. M. A.*, May 12, 1917, p. 1379), bearing upon the nutritive value of several natural foodstuffs in general use, and from which the following summary has been compiled—to present the evidence in concise, non-technical terms. Only such extracts are made as will serve to confirm the claims advanced for the pressing need for greater care, even precision, in selecting the dietary.

The first series of experiments were made upon rats limited to an exclusive diet of corn (*a*) which, in the language of the author, "leads to complete failure of young animals to grow, and death usually supervenes within two months."

Another group (*b*) had butter fat in addition to corn and a third lot (*c*) had corn with clotted milk (casein). A fourth group (*d*) had corn and a combination of mineral salts similar to that found in milk—but there was little growth in any case, the least objectionable diet being that containing the mineral salts.

Then the effects of the addition of two foodstuffs were tested, as follows: (*e*) Corn, clotted milk, and mineral salts, (*f*) Corn, butter fat, and minerals salts; (*g*) Corn, butter fat, and clotted milk.

In the case of *e*, the rate of growth for over five months was less than half the normal, but with the addition of butter fat, rapid growth set in, aud during the following three months two litters of young were born, the second litter being successfully reared.

Case *f*, in which no addition was made, was unfavorable; the rate of growth was slower than normal, she never produced young, and showed decline after the age of six months—lack of protein.

In case *g*, there was no growth at all during a period of six weeks, but with the addition of mineral salts it began, the animal reached full adult size and produced three litters of young, all of which were successfully weaned.

When it is added that these records represent each a group of not less than four rats, restricted to distilled water, the significance of the dietary will be apparent—and the most instructive feature, aside from the function of the fat soluble and water soluble accessory factors, now called vitamines, is the "stimulating" effect of the mineral salts upon growth and reproduction.

The question naturally arises, Does the deficiency of mineral salts in humans lead to physical decadence and mental deterioration? Was the commissary of the logging camp correct in his diagnosis that nitrogenous food in excess leads to sickness, strikes, and fights?

Examination of the wheat kernel shows deficiencies similar to those found in corn—it lacks three essentials required to promote growth, reproduction, and rearing of young, namely, protein, the rebuilding material, mineral salts, and the fat soluble accessory food factor (vitamine). Apparently, the water soluble vitamine is ample in cereals.

The following summary covers the records of a series of investigations in which each group included not less than four rats, the water supply being distilled.

(1) With wheat, clotted milk, dextrin, a gummy substance obtained from starch, and mineral salts, rats grew rapidly to adult size, but all were short lived. When six months old they were emaciated and showed swelling of the eyelids (xerophthalmia) and local hemorrhages—assumed to be due to a lack of the fat soluble vitamines.

(2) With wheat, clotted milk and butter fat, growth was very slow. "After being stunted during five months, on the addition of a suitable salt mixture, the animals experienced a wonderful acceleration of growth, and a complete recovery from a condition of partial baldness, accompanied by a roughening of the skin and tail. Animals in this group have frequently suffered from a purulent bronchitis."

(3) With wheat, salts and butter fat (no casein) there is stunted growth, lack of fertility, and early decline.

(4) With wheat, casein, salts, and butter fat, "it becomes capable of supporting growth, reproduction, and rasing of young which closely approaches the normal." Later, we shall earn something definite about the particular mineral constituent responsible for the "wonderful acceleration of growth" in case 2, especially when we come to study the function of mineral salts in nutrition—a very important question, and one, too, which seems to possess an extreme low visibility.

The oat kernel deficiency is similar to that found in corn and wheat, but "the addition of casein, salts, and butter fat does not lead to normal growth." In a series of three experiments

the growth for three months was near normal, but after that the record shows that the rats lost weight and all were short lived. Limited to rolled oats and casein, or rolled oats and salts, there was practically no growth—and it is stated that normal growth cannot be secured when the oat kernel amounts to 70 to 80 per cent. of the food supply. However, when the oat proportion is reduced to 60 per cent., with the addition of 10 per cent. of gelatin (agar-agar), along with dextrin, salts and butter fat, the growth is fully up to normal—thus showing that gelatin is superior to casein as a protein when combined with oats.

In this connection it will be pertinent to mention the mistaken notion, or superstition, that rolled oats constitute a complete dietary for growing children, because we have precisely the counterpart of the failure in nutrition in the public schools, one-third of the pupils being classed as "backward" or "feeble-minded," the usual addition of milk to the diet being the only redeeming feature. Our author remarks, "We have not yet determined the cause, but it is evident that a high intake of oats over a long period causes injury to the rat. This is true also for the cow, and I believe, also for swine."

The significance of these demonstrations will be appreciated when it is recalled that Atwater's tables show the caloric value of one pound of boiled oatmeal at 285—so that a man would have to eat nearly eleven pounds daily to secure 3,000 heat units!

Of course, it will be claimed that such disastrous results may be avoided if other food materials besides gelatin were combined with oats in making up the dietary, and this is true, provided the supplementary foods are selected from the particular class which supplies a larger percentage of protein, like the leaf, for example. Rats fed on corn, 50 per cent, along with alfalfa and peas, 30 and 20 per cent, respectively, attained full size and the fourth generation was successfully weaned, thus showing that a properly constituted vegetarian diet is quite possible. The advantages of the leaf over the seed are that it contains a larger percentage of a complete protein as well as the fat-soluble essential—and this observation is substantially true and applies generally to food from the leaf.

Only a limited survey of these intensely interesting investigations has been attempted, but it is doubtless sufficient to demonstrate that health maintenance depends upon factors well within the reach of persons of ordinary intelligence—the entire question reverts to the individual, so that his health depends upon his willingness to comply with the deductions warranted and demonstrations made with respect to the essential elements or factors in nutrition. Thus, we have before us as a basis for future study these various elements designated by name, protein, the reconstructive, fat and fat-soluble accessory food factors, carbohydrates (starch and sugar), and the water-soluble accessory food factors. These fat-soluble and water-soluble factors are known as vitamines, the former being found principally in animal food materials, the latter almost exclusively in vegetable foods.

Most important of all, however, is the mineral constituents, as will appear from the following experiments: Rats fed on corn and flaxseed, 90 and 10 per cent. respectively, gained in weight less than one-third of an ounce in four months—they were stunted, "brought to nutritional disaster," but on the addition of mineral salts they grew at the normal rate, gaining nearly four and a half ounces in weight during the next three months—because the mineral salts had restored, or rejuvenated, the functional activity and physical energies of the protein molecule.

Another series of rats had a more liberal diet, at least in respect to variety, namely, corn, millet seed, oats, wheat, and hemp seed, equal parts of each, but gained in weight in the course of three and a half months less than one-eighth of an ounce. On the addition of mineral salts, normal growth set in at once—and it should be added that 40 per cent. of the salts were calcium, or lime.

Confirming this deduction, our author refers to an experiment with dogs, restricted for periods varying from two to eight months to a diet consisting of peas, crackers, and cotton-seed oil. There was sloughing of the mucous membrane of the mouth, diarrhea, ulceration of the stomach, and skin eruptions. Repeating this experiment with rats, with the addition of calcium carbonate (chalk), sodium chloride (common salt), and butter fat, made the diet "sufficiently complete to enable young rats to grow from weaning time to full adult size," the only defect being slight loss of hair.

Applying this evidence to humans, it proves that we may have various untoward physical symptoms from a dietary deficiency which is liable—and likely—to be overlooked or underestimated. In this instance, there was lack of protein, mineral salts, and butter fat, three essentials that are wanting in a diet composed entirely of seeds.

The dietary essentials for both humans and animals include protein, fat, carbohydrates (starch and sugar), and mineral salts, but recent investigations have shown that "accessory" food factors are necessary to supplement these in order to secure perfect nutrition, namely, the fat-soluble and water-soluble vitamines. The vitamines are still unidentified, but their presence has been demonstrated, as illustrated in the preceding summary. Furthermore, these investigations have shed a flood of light upon the cause and treatment of various formidable disorders, some of which have baffled the medical professions for generations—scurvy, rickets and neuritis, for example, and pellagra has been a scourge in Italy and southern Europe for two centuries. It is possible to maintain health only by a careful and critical study of the injurious effects of a restricted dietary, together with correct interpretations, regardless of preconceived notions, popular beliefs, or newspaper display.

For example, pigeons restricted to a diet of polished rice, and distilled water, will die in twenty-one days from polyneuritis, but when in the last stage of dissolution they are given a small portion of a watery extract of the polishings, they quickly revive—in the course of an hour they will be hopping around and apparently in normal con-

dition the following day. In this instance it is assumed that the rice polishings contain the water-soluble vitamine, the endosperm, the albuminous or nutritive substance being merely storage material, protein, starch, sugar, fats, and mineral salts, to provide for the early support of the embryo.

It would be well to recall the deficiency in the oat kernel without the addition of gelatin, because guinea-pigs restricted to a diet of milk and oats will die in six weeks (42 days). When dissolution seems imminent the addition of orange juice will relieve all the untoward symptoms, and the continued use of the orange juice will enable the animals to live and thrive. The factor responsible for this deficiency is still unsolved, but the most plausible theory points to failure of the oats protein to yield the necessary aminoacids—in other words, it is not complete.

Another dietary, limited to seeds (flaxseed and corn), which arrests growth, brings out still further complications, since it has been shown that the addition of mineral salts is quite sufficient to promote normal nutrition. This is a contradiction of McCollum's dictum, as follows: "There are but two types of food mixtures which give very satisfactory results in the nutrition of experimental animals. These are: (1) Combinations in which seeds, tubers, edible roots, and meats are either singly or collectively combined with suitable amounts of the leafy portion of the plant, and (2) combinations of seeds, tubers, roots, meats, and leaves, singly or collectively, with liberal amounts of milk. The leaf, aside from its skeletal tissues, is rich in cells and a large part of it is active protoplasm. There goes with this difference in function between the leaf and the storage organs (seeds) a corresponding difference in dietary properties."

Now, as a general proposition, this is true, but attention has just been directed to one exception, and still another must be noted, in the case where there was perceptibly no growth for three and a half months on a dietary limited to five seeds, namely, millet, corn, oats, wheat, and hemp. Here, also, the addition of mineral salts was promptly followed by normal growth—and it will be worth while in this connection to mention the popularity of a well-known mineral salt (*calcarea ostrearum*) as a factor in the treatment of all chronic diseases. Its scientific position and adaptability are demonstrated by these investigations—and for the very good reason that most of our adult population limit their dietary to seeds, tubers, roots, and meats, the employment of the leaf or milk being rare or occasional; hence, the efficiency of this mineral salt to recoup the deficiency in the protein molecule.

We find an apt illustration of McCollum's theory in the diet limited to corn, peas, and alfalfa, two seeds and one leaf, on which the fourth generation of rats were successfully weaned. Analysis of this dietary shows that it is well balanced to promote nutrition; it is rich in protein and mineral salts, due to the alfalfa and the peas, the corn being lacking in both these essentials, as shown in the following tabulation:

TABLE SHOWING MINERAL SALTS AND PROTEIN.

	Total Ash.	Calcium Per Cent.	Magnesium Per Cent.	Protein Per Cent.
Alfalfa	7.380	2.146	0.223	14.3
Corn (maize)....	1.450	0.009	0.136	8.4
Peas	2.900	0.023	0.034	24.6

Magnesium is included in the table for the reason that this mineral is closely related to calcium as an antacid, catalytic, and reconstructive, and to a certain extent interchangeable; but at the same time they are mutually antagonistic. Water or food containing magnesium in excess as compared with the calcium content, will derange the digestion, impair nutrition, and sooner or later lead to serious involvement of the nervous system. Moreover, this chemical deviation lessens resistance to infection, so that it is rare, indeed, to meet with any of the usual, or common ailments in which substitution is not the prominent, or even the paramount feature.

Some years ago the writer gleaned a valuable pointer from a successful dairyman regarding the *nutritive value of alfalfa hay*. He said he had completely reorganized his plans for feeding the cows because of the demonstrable virtues of alfalfa. Instead of feeding hay and grain he fed alfalfa alone, with the result that he escaped the usual expense for grain, his stock were maintained in better physical condition, the quality of the milk was improved and more uniform, while production was increased 30 per cent.

It is doubtful if corn and peas together would furnish a satisfactory diet for humans, even with the addition of a leaf, such as cold slaw, lettuce, asparagus, or spinach, owing to the mineral deficiency, but this may be overcome by combining with them other food materials carrying calcium and magnesium in the proper proportions. Thus, turnip-tops contain over fourteen times as much calcium as magnesium; whole milk, over nine times; butter, twenty-two times, while cheese contains over twenty-five times as much—and the personal likes and dislikes for these foods is usually a reliable guide in outlining the treatment in chronic ailments.

A diet limited to seeds is certain to produce carbohydrate dystrophy, a condition frequently, if not generally, seen in children, and practically universal in adults, the evidence being the rejections under the selective draft of more than two million men. Naturally, the question will be asked—Who is responsible for this unpromising outlook? Not the medical profession, special dietary instructions to the chronic invalid being regarded for the most part as harmless persiflage—and the public knows too much that is not so.

Defective nutrition, therefore, is not limited to the poor and the ignorant, but it is here that we find the most convincing proofs of the popular fallacies regarding a rational dietary. In the course of a paper, entitled, "Defective Nutrition and the Standard of Living" (*Survey*, March 20, 1918), F. A. Manny, of the New York Association for Improving the Condition of the Poor, presents some pertinent facts which bolster up, if they do not confirm, the experimental studies on animals. He says, "The growth of stunted children can be promoted with almost startling rapidity. The weight charts of the boys in truant schools,

for instance, show almost perpendicular advances as soon as a chance for normal growth is afforded." And he adds, also, "There is a limit to the powers of the food clinic and the dispensary," and "All these measures of relief are social makeshifts compared with the immense work of education and economic readjustment that lies ahead. . . . Unless we recognize that defective nutrition in childhood is only one aspect of poverty and only one aspect of ignorance, and shape our social program accordingly, food clinics and the remedial work of social agencies may only increase the number of children reared in families too poor or too neglectful to be safely entrusted with the reproduction of the race." Evidently, poverty needs an educational splint.

1024 Walnut Street.

PSYCHOANALYSIS.

By H. LAVESON, M.D.,

NEW YORK.

Psychoanalysis is a method of psychotherapy based upon the principle that where there is present marked and persistent impediment in the life of the individual, whether it amounts to the blocking characteristic of nervous disorders or only to such obstruction of effectiveness as is represented in many so-called normal individuals, it is due to the existence in the psyche of unconscious, that is, repressed sexual effects, regressing toward an early infantile mode. The central point of this psychoanalytic principle is that in its basic postulate of repression as the causative factor in the neuroses, we have not to do with a pathological but with a biological principle, and that therefore psychoanalysis does not incriminate the nervous invalid alone, but along with him the whole social organism. It is an indictment not alone of our patients but of ourselves. It does not contrast the normal and the neurotic personality as unrelated genera, but sees unabashed the line of unbroken gradation between these types. The essential idea, then, of psychoanalysis is the personal analysis. It is not the analyis of our patients, it is the analysis of ourselves. If one has lacked the opportunity or the patience or the courage to face the personal analysis in all its rigor, he is unacquainted with psychoanalysis. He is lacking in the essential data. He is counting without his host. It is not, Freud said, the discovery and counting and tabulating of complexes that is the object of psychoanalysis, but the sole object of psychoanalysis is the overcoming of a patient's resistances. A resistance, then, may be described as a blind emotional bias, whereby we are permitted to see things according to preference rather than as the facts warrant. Abrogating the course of intelligence and truth, resistances allow us to blink the facts of life and indulge in pleasanter alternatives. If this, then, is resistance—if this is the obstacle which so crushes the spirit of the neurotic patient and causes him the pain and stagnation of interest characteristic of psychic disorders, it would appear to be the task of the psychoanalyst to liberate the mind of such patient from the incubus of his besetting morality. If fear morality is the stumbling block to the health of the nervous patient, and if fear morality is merely an altered spelling of resistances, the sole recourse of psychoanalysis then is to rid these invalids of their resistances.

Psychoanalysis is the most recent and advanced procedure for the treatment of the neuroses. Other psychotherapeutic methods deal only with the superficial manifestations of the neuroses and therefore cannot produce a fundamental cure. Psychoanalysis concerns itself primarily with the cause of symptoms, with the real underlying mechanism. It not only penetrates into the origin of symptoms, but the analysis at the same time is the treatment. It is a study of man's unconscious motives and desires as shown in various nervous disturbances and in certain manifestations of everyday life in normal individuals. It has been demonstrated that the manifold symptoms of the neuroses result from unfulfilled desires, often extending back to the earliest years of childhood. These desires not only influence the formation of character traits, but likewise are responsible for many forms of nervous illness.

Rightly understood and used, psychoanalysis may be compared to surgery, for psychoanalysis stands in the same relation to the personality as surgery does to the body, and they aim at parallel results. It is well recognized that in the last analysis nature is the real physician, the healer of wounds; but prior to the development of our modern asepsis and surgical technique the healing produced by nature was most often of a very faulty and imperfect type—hideous scars, distorted and crippled limbs, with functions impaired or incapacitated, resulted from the wounds, or else nature was unable to cope with the hurt and the injured one succumbed. Science has been steadily working for centuries so that healing could take place with the least possible loss of function or permanent injury to the individual. Marvelous results have rewarded these persistent efforts, as the brilliant achievements of surgery plainly indicate.

Meantime, however, little thought was given to the possibility of any scientific method being available to help man overcome the wounds and conflicts taking place in his soul; hurts which retarded his development and progress as a personality, and which frequently in the struggle resulted in physical pains and symptoms of the most varied character. That was left solely to religion and metaphysics. Now, however, the same assistance that surgery has given to the physical body psychoanalysis attempts to give to the personality. That it cannot always succeed is as much to he expected, and more, as that surgery does not always succeed, for the analytic work requires much of the individual. No real result can be attained if he has not already developed a certain quality of character and intelligence which makes it possible for him to submit himself to a facing of his naked soul and to the pain and suffering which this often entails. Here, as in no other relation in life, an absolute truth and absolute honesty are the only basis of action, since deception of any kind deceives no one but the individual himself and acts as a boomerang, defeating his own aims. Such deep searching and penetrating into the soul is not something to be undertaken lightly nor to be considered a trivial or simple matter, and the fact is that where a strong

compulsion is lacking, such as sickness or a situation too difficult to meet, much courage is required to undertake it.

In order to understand this psychology which is pervading all realms of thought and seems destined to be a new psychological-philosophical system for the understanding and practical advancement of human life, it will be necessary to go somewhat into detail regarding its development and present status. For in this new direction lies its greatest value and its greatest danger.

The beginning of this work was first published in 1895 in a book entitled "Studienüber Hysterie," and contained the joint investigations into hysteria of Dr. Breuer of Vienna and his pupil, Dr. Sigmund Freud. The results of their investigations seemed to show that the various symptoms grouped under the title of hysteria were the result of emotionally colored reminiscences which, all unknown to the conscious waking self, were really actively expressing themselves through the surrogate form of symptoms, and that these experiences, although forgotten by the patient, could be reproduced and the emotional content discharged.

Hypnosis was the means used to enable the physician to penetrate deeply into the forgotten memories, for it was found through hypnosis that these last incidents and circumstances were not really lost at all but only dropped from consciousness, and were capable of being revived when given the proper stimuli. The astonishing part about it was that with the revival of these memories and their accompanying painful and disturbing emotions, the symptoms disappeared. This led naturally to the conclusion that these symptoms were dependent upon some emotional disturbance or psychic trauma which had been inadequately expressed, and that in order to cure the patient one merely had to establish the connection between the memory and the emotions which properly belonged to it, letting the emotion work itself out through a reproduction of the forgotten scene.

Catharsis, another psychoanalytic method differing from suggestion treatment, has gained recognition during the last few years. The aim of treatment by suggestion is essentially an abolition of disordered ideas, the determination of their cause being considered of little importance. The method of catharsis, however, endeavors primarily to trace the disordered ideas to their source by means of psychoanalysis. The cathartic method presupposes that the patient is hypnotizable and rests on the extension of consciousness which appears in hypnosis. Freud set up as a goal the removal of the disease symptom and attained this by transferring the patient back to the mental state in which the symptom first appeared. Then there came to the hypnotized patient memories, thoughts, and impulses which had previously escaped consciousness, and if he communicated these mental processes under intense expressions of affect to the physician, the symptom was overcome and its return prevented. This apparently regularly recurring experience Freud explains by the fact that the symptoms stood in place of suppressed psychic processes which could not appear in consciousness. The therapeutic efficacy of this method he explained as a discharge of an affect dammed up, as it were, which had remained from the suppressed mental processes. This simple scheme of therapeutic attack was complicated nearly all the time, however, by the fact that not a single traumatic impression, but usually a complex series of such impressions, shared in the origin of the symptom. The chief characteristic of the cathartic method which puts it in contrast to all other methods of psychoanalysis, lies in the fact that in this procedure the therapeutic efficiency does not depend on a suggestive command of the physician. It anticipates rather that the symptoms will disappear if the attempt, which appeals to certain presuppositions concerning the mental mechanism, succeeds in bringing the mental processes into different channels from those they have previously followed in the formation of symptoms.

An entirely sufficient substitute for the cathartic method Freud found in the associations of the patient, that is, in the involuntary thoughts which are mostly perceived as disturbing ones and therefore under ordinary circumstances disregarded; these involuntarily press to the psychic surface in the recital of the patient to the physician and betray the disease complex. He allows the patient himself to determine the theme of the daily work and by this means proceeds from the complex which is present in the foreground of the patient's mind (free association). Thus one receives all kinds of material which belongs to a solution of the symptom, broken into fragments, interwoven in different connections, and distributed over widely separated periods of time; but in spite of this apparent disadvantage the new technique far surpasses the old. In order to strengthen these associations, Freud uses the following outside means of assistance: He has the patient recline comfortably on a couch while he sits on a chair behind and out of his line of vision. He does not insist upon the eyes being closed and avoids any touch as well as every other procedure which might lead to hypnosis. Such a seance goes along like a conversation between two similarly awake persons of whom one is relieved of every muscular tension and every distracting sense impression which might disturb the concentration of the attention upon his own mental affairs. Before he proceeds to details, he urges them often for several sessions to sketch a general picture of their whole illness and most intimate family and life surroundings, to tell him everything which comes into their heads, whether they think it important, irrelevant, or nonsensical. With special emphasis it is asked of them that no thought or association be omitted from the communication because this telling might be shameful or painful.

An experiment which does not require any instruments at all and promises to become of steadily growing importance is "word association." The patient is given perhaps a hundred words, and let him speak the very first word which comes to his mind when he hears the given ones. You call rose, and he may say red or flower or lily or thorn; you call frog and he may answer pond or turtle or green or jump, and if the hundred words are chosen with psychological insight, his hundred answers will allow a full view of his mental make-up. That is not seldom efficient to secure the diagnosis of complex mental variations. The method yields still more if the time for such a reply is measured by

a stop-watch which gives the fifth of a second and is fully sufficient for all practical purposes. From such simple facts of the mental inventory the association experiment may lead to complex questions which slowly may disentangle the confused ideas, for instance, of a dementia præcox, and thus lead to subtle differential diagnosis.

Mention must be made here of the fact that Freud believes dreams to have a certain influence upon the production of functional nervous disorders. For this reason he endeavors by means of psychoanalysis to recall to memory the dream experience which has been dislodged into co-consciousness and to incite the patient to free expression of words. The dream presents itself as a rule as an incomprehensible composition of certain elements which are not in the first instance conscious, but which are later recognized by the process of free association. We may regard the dream as a product that comes from a subconscious origin. The technical unfolding of these unconscious sources is a mode of procedure that has always been instinctively employed.

Many of the dreams of children are manifestly wish-fulfillments. This is also true of many dreams of adults. A child that was sent hungry to bed was heard to murmur in its sleep the names of its favorite dishes. A male patient of mine who lost a very lucrative position seven years ago dreamed recently, the night before he quit a very poor job, that he was back with his old firm and everybody was very glad to see him. Another patient of mine who was robbed by his partners of a contract proving his copartnership dreamed that he found the contract and was reading it with a great deal of pleasure. There are a great many dreams in which the wish-fulfillment is not so obvious but can be easily discovered if one knows all the circumstances preceding the dream. For example, an unhappily married woman dreams that she is again doing bookkeeping for the firm for which she worked before her marriage. A widow who is barred from remarriage because she is burdened with a child, dreams that the child dies of diphtheria. A very tired school-teacher dreams one morning that he is in his classroom giving a lesson. Such anticipating dreams and consolation dreams are very common. Dreams in which a person satisfies some bodily need or which imply that he is free from some malady are obvious wish-fulfillments and promoters of sleep. Thus a thirsty man dreams that he is at a banquet where champagne is dispensed in abundance; a professional acrobat troubled with a boil on his neck dreams that he is performing as usual, etc. Many sexual dreams are so thinly disguised that there can be no doubt as to their meaning, *e.g.* the dream of the man running up the street. If so many dreams easily permit themselves to be interpreted as wish-fulfillments, why may we not assume that wishes are the motive power of all dreams? And if in so many dreams the wish, especially a sexual wish, is represented in a symbolic way, why may we not assume that other dreams too may be the symbolic utterances of the unconscious? At any rate, it is perfectly permissible to put these dreams to the test, and if after such an examination the dreams reveal allusions or references to significant matters or desires in the dreamer's soul and permit an intelligible or meaningful synthesis, there can be no objection to regarding the dreams as the symbolic fulfillment of these desires. If the psychoanalyst's investigations prove, or create the probability, that all other psychic phenomena hitherto regarded as obscure, meaningless, and causeless, *e.g.* neurotic symptoms, certain lapses, reveries, hypnagogic, and hypnopompic hallucinations, spontaneous thoughts, certain forgettings, etc., are definitely determined, *i.e.* are the results of ascertainable unconscious motives, why may he not tentatively assume that dreams too are so determined and may be interpreted by the method he applies to these other phenomena? The free association method, carefully carried out, has proved in thousands of instances that almost all dreams of adults have a latent content and are the disguised and imaginary fulfillment of repressed wishes. The fact, which has been experimentally proved, that hypnotized subjects, ordered to dream of certain matters, do so in a disguised and symbolic manner, also proves that dreams may have a latent content which can be interpreted if one has the key to the dreamer's soul.

Symbolism is a term used in psychoanalysis to express the manner of unconscious thinking in a form in which it would be unrecognized by consciousness. A dream is often symbolic so is often a nervous symptom, when it is an expression of hidden and forbidden wishes repressed in the unconscious. Nervous symptoms are masks behind which a person takes refuge. The symbol is either chosen from the mental content of the individual or it may have a racial or a social basis. In unconscious thinking, the symbols are often used to express sexual concepts which for moral or ethical purposes cannot be expressed literally. The sexual symbols of neurotic patients are therefore efforts to escape from their attachment to the more grossly sexual. Symbols are not invented, they are only discovered. The symbol is not an arbitrary choice, but has its source in the unconscious either of the individual or of the race. Hence the close resemblance between dreams and myths, since the myth is the unconscious symbolic expression of the race and the dream the unconscious symbol of the individual. Symbolism has its origin in the remotest ages of the past. The symbolism of dreams draws its material from this remote ancestry, showing how often the dream is merely a fragment of the mental life of our prehistoric ancestors.

Criticism on Psychoanalysis.—Special objections to psychoanalysis may be raised. With a certain amount of justice it may be said this branch of therapeutics has not yet earned its right to recognition. It may be said that medicinal therapeutics, surgery, all physical means of treatment act by material effects which may be seen, felt, or recognized in some other way. It may be argued that the basis of the psychoanalytic work still is insecure, while the surgeon who removes a malignant growth, opens an abscess, sews up a wound, or ties a bleeding artery is acting in accordance with the requirement of exact science; and the physician who combats an infectious disease by means of the corresponding antitoxin, who reduces fever by a withdrawal of heat, who makes use of quinine in the treatment of malaria, etc., is sustained by medical and physical laws, or, at any rate by practical

experience. It may be contended that in psychoanalysis the material, the physical basis is wanting; that it appeals essentially to the idea, to the power of imagination, to belief; that it makes use of no other method than that of declaration; that it is comprehensible how the medicaments of the physician or the knife of the surgeon produce curative physical changes, but it seems entirely incomprehensible that bodily disorders which have defied other methods of treatment can be influenced by psychoanalysis, by a simple declaration.

Psychoanalysis when employed by the incompetent becomes a curse instead of a blessing. Just as the surgeon must first learn all about the operations which he is to perform and as the physician must know the toxic action of all drugs which he employs, so must the psychoanalyst be well informed as to the numerous precautions which the practice of his branch entails. Every specialist at least must have such knowledge of his special branch as will enable him to make correct diagnoses and to institute proper treatment in extraordinary cases, and to do that with greater precision and certainty than can be expected of the general practitioner. What would be thought of a surgeon who is not thoroughly versed in topographical anatomy, or who is not master of the operative technique? What of the clinician who cannot differentiate a bronchial from a cardiac asthma? Similarly the psychoanalyst has missed his vocation if he is not the possessor, in addition to a good general medical education, of special knowledge of the psychophysiological laws, of the functions of the mind and the nervous system and their reciprocal relations under physiological as well as pathological conditions.

Special precautions are required in the use of hypnotism. Incorrect employment of it may bring about permanent harm. Through hypnotism the impressionability for suggestive influence becomes increased. The person in that state, consequently subordinates his will to that of the hypnotist more readily than during the working state. Hysterics who have been frequently hypnotized acquire an augmented suggestibility, not only in their relations to the hypnotist but to every one else, so that even in the ordinary occurrences of everyday life their thoughts, feelings, and actions may be swayed easily. Such subordination of the will must be prevented under all circumstances, for the only justifiable object of suggestion and hypnosis must be to effect a cure. Once that object is ignored all dangers incident to psychoanalysis will surely arise. The personality of the physician exerts an extraordinary influence on the efficiency of therapeutic procedures. Certain qualities must be possessed by the psychoanalyst which are not necessary for the practice of other branches of medicine. Above all, the practice of psychoanalysis requires special preparation. Absolute essentials are a theoretic knowledge of neurology and psychology, a practical knowledge of the general clinical and anatomical peculiarities, and a special knowledge of all the details of functional disorders and functional symptoms. Only the trained neurologist and the psychiatrist, therefore, are qualified to practice psychoanalysis.

In psychoanalysis everything depends on a proper understanding between physician and patient. The physician must be able to follow the train of thought and the emotions of children and adults, of the cultured and uncultured, of the rich and the poor. If their ways of thinking and feeling be strange to him, how can he gain the confidence of his patients, or elicit the frequently abstruse history of their disease or give them proper instructions? To secure the acceptance of this word, to effect receptive adoption of his suggestions by patients of the most varied degrees of education and refinement, the psychoanalyst, more than other physicians, must possess a high degree of knowledge of human character and a vast experience of life.

Nervous, excitable persons are particularly unadapted as psychoanalysts, for the ability to concentrate his thoughts is necessary not only for the patient who is to be influenced, but also for the physician who desires his suggestion to be adopted. He who wavers and doubts his own capabilities, he who does not himself believe in the effectiveness of psychic treatment will never gain the confidence of his patients. The psychoanalyst who is the fortunate possessor of natural and acquired qualifications cannot fail to cull the fruits of conscientious endeavor.

Application of Psychoanalysis.—We might begin this large group of the constitutional disturbances with that neurasthenia which develops on the basis of inherited disability. Lack of energy resulting from a feeling of tiredness, a quick exhaustion, a mood of depression, an easy irritation, even despair and self-accusation, sullenness and fits of anger, "cranky" inclinations, and useless brooding over problems, headache and insomnia characterize the picture which everyone finds more or less developed in some of his acquaintances. If we classify symptoms, we may separate from it that which we nowadays are inclined to call psychasthenia. An abnormal suggestibility for auto-suggestions stands in the foreground. Fixed ideas and fixed emotions, especially fears, trouble the patient. He may pick up his obsession by any chance experience and no good will liberates him from the intrusion perhaps for years. The patient is perfectly well aware that his ideas and his emotions are unjustified, he himself does not believe in them, and yet they come with the strength of an outer perception and with the vividness of a real attitude, and his whole mental equilibrium may be upset by the continuous fight against these involuntary influences. In the light cases, sometimes the one and sometimes the other auto-suggestions may hold the stage; in the severe cases, mental life turns more and more around certain definite fears and yet it may all still be in the limits where the daily work can go on, and the world may not know of the hidden tortures. Here belongs the fear of open places or the fear of touching certain objects, the fear of doing harm to others or the fear of deciding actions wrongly, the fear of destroying valuable things or the fear of being the center of public attention, the fear of crowds or of closed doors, of altitudes or of bridges. And in all cases emotional reaction may set in with anxieties, and bodily symptoms, such as palpitation of the heart, may result, whenever an effort is made to disregard the nervous fear. There is perhaps no group of patients who so much de-

serve the most careful efforts of the psychoanalyst. Still more than the hysterics, they suffer from the fate of seeing their ills counted as not real. For them everybody has the good advice that they ought to overcome their fancies; and yet they feel their life ruined with their endless fight against the overpowering enemy. And if anywhere, it is here that the psychoanalyst is successful. Psychasthenic fear can be removed, while the developed melancholic depression, for instance, is entirely beyond the reach of practical influence.

We have after all the same psychasthenic state before us when the obsession has impulsive character, from the mere abnormal impulse of lying, or making a noise in a quiet place, or crying in the dark, or touching certain places, to that of stealing, indecent speech, arson, and perhaps even murdered. The symptoms might easily be mistaken for those of graver diseases. Yet the fact that the patient himself really does not will the effect at which he is aiming separates, mostly without difficulty, the diagnosis of psychasthemia from that of insanity. Quite nearly related to it are the manifold variations of abnormal and perverse sexual tendencies. The psychiatrists are perhaps too much inclined to bring all these pathological impulses and desires, fear, and anxieties, into the nearest neighborhood to real insanity. The indisputable success of psychoanalysis in these spheres ought to add a warning against these expansions of the strictly psychiatric domain. The psychologist will be more inclined to emphasize their relation to simple neurasthenia which itself imperceptibly shades over into our normal life.

All neurasthenic and psychasthenic disabilities show a certain emotional continuity and uniformity. It is the emotional instability, and the quick alternation of symptoms which characterize hysteria, or rather the hysterias. It seems as if science were near to the point of explaining the hysterical disease by one common principle, but certainly the symptoms are an inexhaustible manifold. The rapid changes of the intense moods of the patient usually stand in the center. Torturing obsessions, abnormal impulses, oversuggestibility, hypochondriac depression, paralysis of arms or legs, anesthesia and paresthesia, a mental stupor and confusion, illusions, and perceptions of physiological symptoms may work together in spite of his, or rather her clear intelligence. It is probably on an hysteric basis also that somnambulic states arise during the night, and from them a straight way leads to those mental attacks after which the memory is entirely lost, or for which fundamental associative connections are cut off. And from here we come to the exceptional cases of alternating personality. The more we recognize the myriad symptoms in the hysteric patient as products of the emotional instability of autosuggestibility and of inhibition, the more we understand the almost miraculous result of psychoanalytic treatment. Autosuggestions can be fought by counter-suggestions, anesthesia and paresthesia can be removed often in an instant, dissociated personalities may be built up again through hypnotism, the most severe bodily symptoms may disappear by influences in a waking state. Hysteria alone would justify the demand that every physician in his student days pass with open eyes through the field of psychology. Quite near stand chorea and the epidemic impulses to initiative movements. And we might bring into this neighborhood also the disturbance in the equilibrium of the speech movements through all degrees of stammering and severe impairment. Up to a certain degree, though not often completely, they too yield easily to psychoanalytic influence.

We enter now that region of constitutional disturbances in which psychoanalysis is of small help. It leads from epilepsy to the periodic diseases, especially the maniacal depressive insanity, the paranoia which develops late, and finally to states of idiocy which cover the whole life. We are far from claiming that psychic influences are entirely powerless, the more as we insisted that psychoanalysis goes much beyond mere suggestions and appeals. No psychiatrist will work without psychological tools when he deals with the exultations of the maniac and the depressions of the melancholic, with the hallucinations of persecution or the erotic insanities of the paranoiac. Still more the whole register of psychology has to be used, when we are to educate the idiot and the imbecile. But the disappearance of the disease or of the chief symptoms through the mental agencies is in all these cases out of the question. Only in incipient cases, especially of melancholia and mania, the psychoanalytic work seems not entirely hopeless.

We have reviewed the whole field of psychophysical disturbances, those produced through external conditions in the normal brain and those resulting from abnormal brain constitution. We have seen that the work of the psychoanalyst is of very unequal value in different parts of the field; in some, as in neurasthenia, in psychasthenia, in hysteria and similar regions, most effective, in others, like paresis or paranoia, reduced to an almost insignificant factor. Where it can help and where not we recognize as a mere question of experience. Certainly the severity of the symptoms alone does not decide it. As the treatment is entirely empirical, no one can foresee whether or not the situation may change tomorrow. We may find psychoanalytic schemes by which maniacal depressive insanity or traumatic neuroses may become accessible. We simply do not know why we may remove stammering or synthesize a dissociated personality or overcome an inborn sexual perversity, while we are unable to remove the depression of the melancholic. Certainly the symptoms of the circulatory insanity disappear completely in the free intervals; there is no reason to give up hope that psychoanalysis might find the way to hasten the appearance of such a normal period.

511 East Eleventh Street.

MYCOTIC OTITIS.*

By C. J. KOENIG, M.D.,

PARIS, FRANCE.

OTO-RHINO-LARYNGOLOGIST TO THE AMERICAN HOSPITAL OF PARIS.

Mycotic infection of the ear, although well known, is not of very frequent occurrence. This communication has therefore not the pretension of

*Read before the French Oto-rhinolaryngological Society, May 15, 1919.

adding anything new to the subject, but by a few details and considerations, may possibly be of interest to those who have not observed similar cases. The possibility of mistaking them, when accompanied by perforation of the drum, for a suppurative otitis of microbial origin, renders the study of these cases interesting and shows how useful it is to know how to detect them early for the good of the patient, their cure being obtained easily in the majority of cases and in a short time.

A young woman, 27 years old, in her seventh month of pregnancy, with cicatrized pulmonary lesions of tuberculous origin, according to her physician, consulted me, after having been treated by the latter during a few days for eczema of the right external auditory canal. She informed me that she had suffered from violent pains in the right ear a few days previously, which had diminished since, and that she still experienced a feeling of uneasiness, with tinnitus, itching, and deafness.

Inspection revealed a canal full of whitish or greyish masses, which I took for macerated epithelial débris and which I removed with the syringe. The internal aspect of the canal and the drum membrane were red, the latter perforated in its antero-inferior segment. Catheterization of the Eustachian tube blew out secretions from the middle ear, and I diagnosed the case as one of acute perforative purulent otitis media dextra which explained the previous violent pains, pains in all probability relieved by the perforation. I treated the patient during thirteen days by catheterization, syringing of the external auditory canal, and instillations of alcohol and peroxide. The perforation closed, the drum membrane and canal became normal, and the hearing returned.

Three weeks later the patient appeared again complaining of uneasiness and itching. Inspection again revealed masses of débris which I again took for desquamated and macerated epidermis. After a washing out the symptoms at once disappeared. There was no perforation. She returned again fifteen days later suffering from atrocious pains. Inspection revealed the same conditions as on the two previous occasions. After syringing, the drum membrane presented a peculiar aspect. There was no perforation, but on a very red background could be seen four little white dots as big as an ordinary pin head surrounded each by a whitish halo; the canal near the drum presented the same aspect, and on its anterior wall was a small furuncle which slight pressure with a cotton swab evacuated. In the pretympanic recess there was a slight yellowish secretion which a smear showed under the microscope to be made up of abundant polynuclears and containing diplococci. After cleaning and drying the canal and drum membrane, I insufflated a little lacteol powder and asked the patient to return the next day. The same treatment was repeated. The day after this the situation became interesting. On inspection I saw the white lacteol background besprinkled as with powdered coffee or snuff. I immediately thought of an animal or vegetable parasite, of eggs or spores.

Under the microscope this brown or black powder proved to be spores in the form of discs absolutely round with regularly crenelated edge, smaller than red blood cells. They resembled small pinion wheels. Their surfaces were excavated in the center, cup-like. These spores had therefore grown in the space of twenty-four hours. Fearing they might be impurities contained in the lacteol powder, I examined the latter product under the microscope, but did not discover therein the slightest trace of spores or mycelium. I touched the drum membrane and the whole surface of the auditory canal with alcohol, 90 per cent., and the next day the membrane and canal were found to be normal. I asked the patient to return in a few days and to resort to no treatment in the interval. As I was sure the trouble would return, I procured a few tubes of peptonated glucosated gelose of Sabouraud and, a few days later I made a culture from the patient's ear and obtained a beautiful growth of black spores resembling snuff on a greyish base constituted by the mycelium. I removed from the auditory canal a few greyish masses which I had taken previously for macerated and desquamated epithelium, crushed them between two cover glasses, and the microscope showed them to be intricate meshes of mycelium containing spores.

The cultures on Sabouraud's medium developed very rapidly. In forty-eight hours there was already a growth of mycelium surmounted by black spores.

Examination showed the growth to be typical *Aspergillus niger*, which, of all inferior moulds, is the one which develops most frequently in the external auditory canal. That rapid growth of spores is most remarkable and contrasts with the development of other black spores, which become brown or black only after a certain number of days, such as the spores of *Sporotrichum beurmanni*, which at first of coffee and milk color, become chocolate brown, and finally black. Moreover, they are ovoid or piriform, whereas the spores of *Aspergillus niger* are round and black at once. In chalarosis the colonies are at first pinkish and little by little become brownish.

An interesting point in this case is the previous pulmonary tuberculosis, now cured. We know today[2] from the researches of Rullmann, of Di Donna, of Petruschsky, of Bory and H. Roger, of Aoyama and Miyamoto, of Norris and Larkin, et al., that cases of pulmonary mycoses exist which simulate tuberculosis and that examination of the sputum shows acid-fast bacillary forms simulating the bacilli of Koch. On the other hand, the bacilli of Koch frequently take on mycotic forms, as shown by the researches of Pétrone, of Metchnikoff, of Czaplenski, of Fischel, of Coppen Jones, of Babès and Levaditti, of Fromme and of Sanfelice, and to such an extent that quite a number of authors think that the tubercle bacillus should be classed, not with the bacteria, but with the moulds. At any rate, these considerations allow me to entertain a doubt as to the tuberculous nature of the previous pulmonary affection of my patient, now cured, and this aspergillous mycosis of her ear tends to justify this doubt with the thought that the patient in question is particularly sensitive to mycotic affections.

The comparison of bacterial and mycotic affections from the double viewpoint of pathological anatomy and symptomatology is quite interesting. In the present case there were inflammation, suppuration, and destruction with the subjective symptoms of pain, tinnitus, and deafness resembling a bacterial suppurative otitis. It is therefore evident that analogous lesions due either to bacteria or moulds have very analogous consequences when they have the same localizations. This analogy has become even more interesting and evident since the discoveries of Charrin and Ostrowsky, of Roger and Concetti, of Auclair, of Ceni and Besta, of Bodin, Gautier, and Lenormand, of Gougerot and Blanchetière, have shown that moulds of different kinds (*Oidium albicans*, *Actinomyces*, *Aspergillus fumigatus* and *flavescens*, *Sporotrichum*) contain toxic substances which, when injected into animals, produce inflammatory phenomena. Plato, Mario Truffi, Bruno Bloch, Pautrier and Luthembacher, Beurmann and Gougerot obtained with them on patients local and general specific reactions, and Widal and Abrami have been able to make the serodiagnosis and the fixation reaction on patients infected with sporotrichosis.

According to Bodin[3], the lesions produced by mycoses are the following: The elements of moulds which develop in the tissues produce a mechanical alteration, a sort of dissociation of the elements of those tissues, and around the parasite a cellular reaction takes place in the form of an infiltration of various leucocytes in the derma and hypertrophy of the fixed elements, vascular dilatation and manifest endothelial alterations. All these phenomena, which are the result of a cutaneous defensive reaction in the presence of the parasites, constitute the simplest degree of mycotic lesions. With certain moulds the reaction is more intense and more acute, the reactional type is distinctly inflammatory, with abundant polynucleosis ending in the formation of purulent collections. Trichophytosis with deep dermatitis and suppurative folliculitis is one example. The case of my patient with suppuration and perforation of the drum is perhaps another one, in spite of the fact that in the pus were found a few diplococci which took the methylene-blue stain.

We are now acquainted with the cases of suppurative dacryocystitis (Nedden), of purulent conjunctivitis (Fullerton and Jones), of tonsillar abscess (Roger and Bory), caused by moulds. These pathogenic moulds, according to Bodin, therefore often deserve to be placed on the list of pyogenic germs.

As to the treatment, rectified alcohol gave in this case the marvellous result which Hassenstein and Küchenmeister obtained with it in similar cases, as reported by Politzer in his book.

It suffices to allow the alcohol to remain in the ear for fifteen minutes in order to find the next day the drum membrane and external auditory canal completely decongested and to cause the sensation of uneasiness and of itching to disappear. This treatment was repeated twice daily for a few days, and then once a month for a few months to prevent a relapse. It might be well to add to the alcohol a minute quantity of nitrate of silver, for in infinitesimal doses (1 to 1,600,000), it prevents the development of the spores of *Aspergillus niger* in the medium of Raulin, which is so favorable to the culture of the plant. Raulin has even observed that the spores do not germinate in his medium when contained in a silver vase, even though chemical analysis, however delicate, cannot reveal the slightest trace of silver in the medium (Bodin).

Chinese Red Cross.—The Chinese Red Cross is to-day an organization with 25,000 members, whose interest in world relief work is evidenced by the entrance of the society into the League of Red Cross Societies. The Chinese have been much impressed with the work of the American Red Cross both during and after the war, and China now desires to take her place beside the other nations of the world in the work of relieving human suffering.

THE PHYSICS OF PERCUSSION.

By ALBERT ABRAMS, A.M., M.D., LL.D.,
SAN FRANCISCO, CAL.

In a recent communication, "*L'orientation des animaux et les influences magnetiques*" by Regnault before the Society of Comparative Pathology (Séance of July 8, 1919), the following observation was made: "My studies on orientation have been controlled by the observations of Abrams."

"To obtain the best results, subjects must stand on a grounded plate and colors and intense light must be avoided. Under these conditions my investigations with colleagues at Vichy, Granville, and Toulon show the following: When the heart area was defined by percussion (patient facing west) then percussed again the patient facing east, north, and south, the area of dulness was notably diminished in the latter positions. The liver border in the right parasternal line diminished 2 to 4 cm., and the upper heart border was lowered from 8 to 10 mm. when the subject was turned from the position "face to the west" to the position "face to the north." We proved Abrams' studies which show that the visceral reflexes[1] attain their maximum reaction from electronic energy[2] when the subject faces west." The writer[3] has expressed himself as follows: "Tone is an essential attribute of all living organisms and relaxation is its antithesis. The nerve centers are in a condition of tonic excitation from which impulses pass to the viscera maintaining them in a state of tonic stimulation. Every living being transforms energy from the universe. The ideal man is a perfect transformer and 'Life is a continuous adjustment to the environment' (Spencer). The attraction of man by the sun and the mechanical energy imparted to him by the sun, rotation of the earth, atmospheric pressure, and the electric potential at billions of volts all influence the microcosm by the macrocosm—the world machine."

The writer has shown that the magnetic elements influence visceral tonicity and that the output of energy varies in relation to the posture of the individual because the intake of energy is similarly influenced. The organs are in a varying state of tonicity and the tone may be normal (orthotonic), increased (hypertonic), diminished (hypotonic), or absent (atonic). *A relaxed organ will yield a smaller area of dulness than an organ which is in a state of tone.*

To reproduce accurately the area occupied by an organ it must possess tone, otherwise topographic percussion is unreliable. It is easy for the physician to show that the borders of the heart will vary according to the posture of the patient on whom percussion is executed. It will be found that the area of the heart or for that matter any viscus will be greater when the patient faces the geographic west than when he faces the other points of the compass. Note that, when the patient stands in the *magnetic meridian*, supreme tonicity is conferred on the viscera. The latter maneuver is equivalent to organismal induction from cosmic energy. The writer wishes to emphasize an important fact in the technique of sphygmomanometry (like percussion) viz., the necessity of taking pressure in a definite position.

Any physician can easily prove that variations (however slight) do occur and they are most manifest when the patient faces the geographic north when the time pressure is taken. Vital phenomena are dynamic and organismal action is a process, not a structure. All problems dealing with the physiology of man not in accord with the progress made in physical science are doomed to perish.

In the writer's book,[3] the electrophysiologic structure of man is shown with the hands and feet as polar termini. With an apparatus constructed by the writer (electroradiometer[4]) it can be definitely shown that the polarity of the hands and feet of a normal male is positive on the right and negative on the left side; this polarity is reversed in the normal female.

Let the reader forget for a moment that the latter observation is correct and try the following: Percuss the area of the heart with the patient facing the geographical west. Instruct the patient to bring both feet in apposition. (Note that the area of the heart is diminished.) Instruct the patient to approximate his finger tips in addition to his feet, and note that in many instances the area of cardiac dullness on light percussion is practically annihilated.* Note furthermore that, the moment the feet of the patient are approximated, there is a momentary inhibition of the pulse. Also observe the following: (1) Deep percussion shows cardiac dilatation; (2) Transitory mydriasis; (3) Augmented visual and auditory acuity (slight); (4) Slight collapse of small veins; (5) Heart tones less loud; (6) Increased dilatation of aneurysms. Any metal uniting the cerebral hemispheres will produce like effects.

If arms are fully extended from body and feet separated (patient facing west) greater tonicity is conferred on the viscera, viz., (1) Heart tones stronger; (2) Heart and liver borders recede (2 cm.) and the lower lung border about 3 cm.; (3) Venules enlarge. Non-recognition of the foregoing heretofore unrecognized data will greatly influence the findings of the clinician and roentgenologist.

Periodical attacks of cardiac dyspnea may be due to short-circuting.

We have ignored environmental energy in controlling the nervous system—influence of light on the retinal receptors, sound (cochlear ending), gaseous substances (olfactory cells), temperature changes, etc. In brief the human mechanism owes its maintenance to the action of many external forces. By aid of the author's apparatus (oscillophore), it can be finally and definitely shown that the energy emanating from the body is magnetic.

When the feet and hands are approximated the maneuver may be likened (in the animal machine) to a short circuit in a dynamo which discharges the current within the machine thus causing its deterioration and minimizing its energy output.

Let percussion of the heart teach us another lesson in the physics of the human organism. The "reflexes of Abrams" demonstrate that the earth is the negative terminal of nature's energy. That, when the electrical tensions between the body and earth become equalized the maximum tonicity is conferred on the viscera.

Ground each leg of patient by means of a wire to a faucet or radiator and note that the intensity of cardiac dulness is greater after than before grounding.* Note also the effect when patient approximates his feet and hands and note furthermore, that the maximum intensity of cardiac dulness is attained when the patient is grounded and stands in the magnetic meridian.

The writer has utilized therapeutically the latter data[5] for the purpose of minimizing the expenditure of nervous energy in neurasthenia.

A maximum amount of energy may be conferred on the viscera by aid of the writer's oscilloclast.[4] It will be noted by the investigator that when the fingers and feet of the patient are approximated owing to the removal of vagus tone, the lower lung border will descend several centimeters. The "lung reflex of dilatation" thus induced will render areas of lung consolidation less evident.

To aid topographic percussion, the methods of transsonance[6] and suppression of the vibrations of the sternum[6] will prove of great value.

A recent method of "threshold percussion" first utilized by the writer is of undoubted value in defining the areas of visceral dulness and the areas of diminished resonance elicited by the electronic reactions. In lieu of the conventional method of finger-finger percussion (percussion on a single finger), the index and middle fingers are crossed and percussion is executed on the terminal phalanx of either the superimposed index or middle finger. The clinician can readily convince himself of the superiority of this latter modified method of percussion.

*Those executing the "electronic reactions of Abrams" should bear the fact in mind that approximation of the feet and hands (of patient, subject, or both) will prevent the electronic reactions.

*In the writer's research laboratory, the patient stands on two plates of aluminum which are grounded.

REMOVAL OF A VERTEBRA OF A CHICKEN FROM THE ESOPHAGUS.

BY JOSEPH EASTMAN SHEEHAN, M.D.,

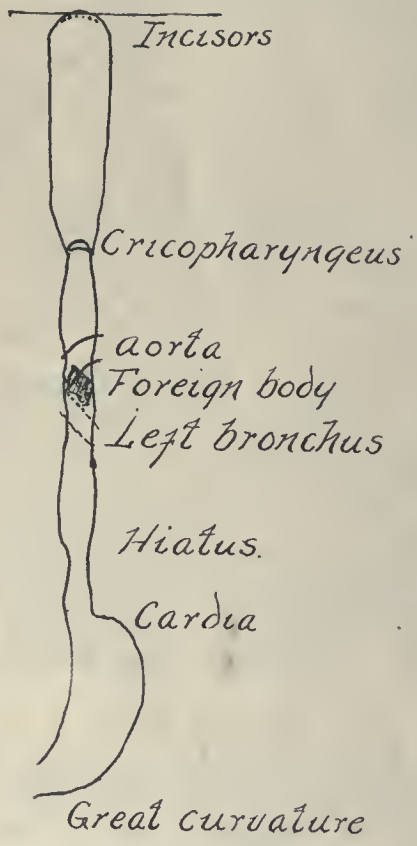
NEW YORK.

ON December 2, 1919, I examined Max L., age 64 years, at the Post-Graduate Hospital. He stated that several nights previous, while at a reception dinner given in his honor, he suddenly swallowed a large piece of the neck of a chicken. This was followed by pain and inability to swallow food or water. The pain gradually became worse and localized itself in the midsternal region. The pain and inability to swallow food or water caused great suffering.

A fluoroscopic examination was made by Dr. Meyer and an obstruction to the esophagus was noted at about the second constriction of the tube, the object being about one-half inch in diameter and almost cylindrical in shape. The nature of the foreign body was not demonstrated on the plates.

An esophagoscopy was performed by me under cocaine anesthesia. I immediately came down upon the foreign body, which was situated between the second and third constrictions of the esophagus, that is, the area where the esophagus is crossed above by the aorta and below by the left bronchus. This location is shown in the accompanying diagram, after Jackson. The esophageal wall above the obstruction was lacerated, somewhat gangrenous, and there was a foul putrefying odor present.

I grasped the foreign body and with a very gentle side movement with upward traction I finally freed it from its bed and successfully extracted it. It proved



to be a vertebra of a chicken. The area where the foreign body was imbedded was deeply ulcerated, gangrenous, and there was a nauseating odor. This area was gently probed and showed that the muscular coat of the esophageal wall had been attacked. The whole ulcerated area was freely mopped with a freshly prepared 25 per cent. argyrol solution.

In these ulcerated conditions of the esophagus I generally insert an Einhorn duodenal feeding tube and the patient is fed through it. But as a tube was not at hand, rectal feedings were started and the following preparation was given by mouth three times daily dissolved in water:

Argyrol crystals	0.6
Bismuth subnitrate	2.0
Magnesia usta	0.6

At the end of the third and sixth days esophagoscopy was again performed and the ulcerations were treated by direct applications. After ten days the patient left the hospital none the worse for his very trying experience.

The main reason for reporting this case is to show the great necessity of performing an early esophagoscopy in all cases with the history of swallowing a foreign body. The danger of complications of extensive gangrenous ulceration, resultant fibrosis, and perforation of the esophagus is thereby greatly reduced.

24 East Forty-eighth Street.

Medicolegal Notes.

Effect of Blow While Working Under Extreme Heat.—A city employee, engaged in assisting in loading with a shovel slag upon a wagon, received a slight blow in the neck in the course of his employment, from the end of a shovel handle in the hands of a teamster who was leveling the slag thrown upon the wagon, either by the employee walking against it or by the teamster pulling it back in the course of his work. It was not such a blow or contact as to cause any abrasion or make any mark or bruise upon the skin. Immediately after, however, the employee became sick; was given some assistance by his fellow workmen; was later, during the same afternoon, taken to a physician's office. On the following morning paralysis had developed so as to be, as stated by the doctor, complete. The employee claimed compensation under the Utah Workmen's Compensation Act. The question was whether the evidence supported a finding of the Industrial Commission that the injury resulted from an accident received while in the course of the employment. The conclusion of the commission was: "In view of the extreme hot weather, age of the applicant, and the obvious susceptibility of applicant to suffer a paralytic stroke at the time of the accident, the fact that no evidence of sickness or distress was apparent immediately before the blow, that a strange feeling, sickness, and a paralytic stroke developed in usual time immediately following the blow, it is reasonable to conclude that the blow from the shovel, received accidentally and arising out of and in the course of his employment by the defendant corporation, was the proximate cause of the disability suffered by applicant, and an award of compensation should be made accordingly." It was conceded that if the award could be supported such support must be found in the testimony of the attending physician, as his was the only testimony that connected the paralysis with the accident. This testimony, set out in the court's opinion, was to the effect that the applicant, from tests afterwards made, apparently had a high blood-pressure at the time of the accident, augmented by his working under a terrific heat and the injury was started by his being struck in the neck. The court sustained the award.—Murray City v. Industrial Commission, Utah Supreme Court, 183 Pac. 331.

Harrison Narcotic Act—Intent in Selling Morphine Sulphate.—Under an indictment for violation of the Harrison Narcotic Act, by selling morphine sulphate without the prescribed orders, and by buying it for illegal purposes, the defendant being a physician but not registered as a dealer in the drug and not having paid the special tax, as required by section 1 of the act, it was held by the Circuit Court of Appeals, Third Circuit, that, as he had dispensed the drug to persons without the written orders required by section 2 of the act, and had also, by means of the statutory order forms, obtained large quantities of the drug, he was guilty of the violations charged unless it appeared, in the one case, that the drug was dispensed or distributed in good faith, in the course of his legitimate professional practice, and in the other case that it was acquired for use therein. It was also held that, although the Harrison Act was passed pursuant to the taxing power of Congress and is clothed in the garb of a revenue act, the judge did not err in charging that the purpose of the act "is to restrict the distribution and use of opium and its derivatives to medicinal purposes only."—Trader v. United States, 260 Fed. 923.

Physical Examination by Physicians in Negligence Cases in New York.—The Kings County Court, New York, holds that although there may be no objection to the physician disclosing to the defendant the results of an examination made by order of the court in a personal injury action, under New York Code of Civil Procedure, § 873, the court has no power to direct him to make such report to the defendant.—Herbert v. Brooklyn Heights R. Co., 177 N. Y. Supp. 901.

The same court vacated an order granted under this section for physical examination of plaintiff before trial in a negligence action, which provided that "the report of the physician be given to counsel for the defendant."—Tutone v. New York Consol. R. Co., 107 Misc. 571, 177 N. Y. Supp. 818.

THE REVERSAL OF THE HEAVY METAL-PROTEIN REACTION.

THE salts of the heavy metals are for the most part quite poisonous and this action is thought to be due to their ability to coagulate and so denature the body proteins. It has been generally believed that this reaction is irreversible and that a cell so injured cannot be restored to normal. On the basis of this belief poisoning with such salts has been treated by attempts to render the poison insoluble and thus limit its action and in addition to treat the patient symptomatically, the latter being chiefly confined to favor elimination and to combat the acidosis which frequently appears.

Kehoe, one of Fischer's pupils, has, however, been carrying out experiments which seem to indicate that this reaction between the salts of the heavy metals and the proteins is not irreversible, and thus holds out hopes that treatment may be directed to reversing this precipitation and thus restoring the normal colloidal condition of the body proteins. He has made his experiments (*Jour. Lab. & Clin. Med.*, 1920, v, 443) with a 2 per cent. "solution" of gelatin. Various salts were used to produce coagulation. These were silver nitrate, copper sulphate, ferric sulphate, lead chloride, mercuric chloride, and others. The reversing agents were found to be neutral salts of the lighter metals and the alkali hydroxides. These agents were added to the coagulated gelatin 48 hours after the heavy metal salts had been added, and their action was apparent in 24 hours. Kehoe used a large number of salts as reversing agents and in all instances obtained resolution of the heavy metal coagulum. The completeness of this action depended upon the strength of the resolving solution and the time and the temperature in which it acted. The nature of the acid radical seemed also to influence the speed of the reaction. Resolution was obtained first with hydroxide, next with sulphocyanate, and then iodide. The others were much slower, the bromides, chlorides, nitrates, citrates, and acetates arranging themselves in the order named. Similar results were obtained on a small scale, using casein in place of gelatin.

The author's theory as to the action of these solutions is that coagulation is due to the formation of particles of poorly hydrated and insoluble metal proteinates and that the replacement of the heavy metal by the light one results in a light metal proteinate which is more highly hydratable and soluble. If his conclusions are justified then we have an important application in the treatment of poisoning with the heavy metals. Even should it be shown that in the reversal of these reactions the end-product is not a normal protein, still in it the heavy metal is apparently bound in a form in which it is unable to denaturize proteins. The author feels that the long use of potassium iodide in the treatment of chronic lead poisoning is an evidence of the beneficial effect of such treatment as he thinks may be recommended. He also suggests that according to his theory it may be unwise to use potassium iodide at the same time as mercury or arsenic in the treatment of syphilis because it may hinder the action of the metal upon the causative organism. He points out that in the treatment of metallic poisoning the salts should be administered in what would be considered huge doses and that the bicarbonates would be of value both for overcoming acidosis and for reversing metal proteinates. It is an interesting presentation and should be subjected to experimental tests at an early date.

THE PROGNOSIS OF CANCER OF THE MALE BREAST.

IT is an established fact that a non-malignant tumor tends to transform malignantly and that a malignant neoplasm when left alone ends in death more or less rapidly according to its power of generalization. In the connective tissue growths the greater the proportion of embryonal tissue, the greater the malignancy; in epithelial growths, the cell masses infiltrate all the surrounding structures while the generalization is such that the case becomes quickly inoperable. Therefore, surgical interference should be resorted to without delay, but although the immediate results seem excellent, this cannot be said of the ultimate results. In the male as in the female recurrences are common. Statistics show that they can be estimated at 60 per cent. and the first recurrence does not ward off the advent of a second or a third recurrence, should the patient survive long enough. Williams, who endeavored to find the average time elapsing between the operation and the first recurrence, came to the conclusion that in the average, nine months will pass before the recurrence takes place, the maximum being hardly ever more than thirty-five months and the minimum he found was six weeks. Of twenty-four cases in the male, Jamicy found that in nine a recurrence took place in three months after the operation, in eleven from eight to fourteen months, and in two more than twenty-four months.

In the recurrences, the new growth presents the same pathological type of growth as the original neoplasm in the mapority of cases. It consequently seems logical to suppose that the recurrence is, at

least in a general way, a continuation of the initial neoplasm. Poirier did, indeed, report two cases of scirrhus cancer of the male breast which gave rise to the encephaloid form in the recurrence, but it should be remembered that it still remained an epithelial cancer and that between these two forms there exists only a quantitative difference in the masses of epithelial cells which are very few in number and very small in size in scirrhus, while in encephaloid they are present in considerable masses.

Some instances of recurrence in the opposite mammary gland have been recorded in the male, but in the majority of cases this takes place in the cicatrix of the operative wound or in the axillary lymphnodes. A recurrence in the cicatrix is rated at 15 per cent. of the cases and it is probable that on the hemostatic forceps rests the guilt of transporting the neoplastic cells which later on proliferate. The frequency of this form of recurrence has, we believe, considerably diminished in women since more care has been taken in carrying out a rational technique of cancer of the breast. As to recurrence in the lymphnodes, they are explained by the fact that the microscope has shown that often apparently normal lymphnodes are in reality infiltrated with cancer cells. Therefore, it is not permissible to give a better prognosis in the case of cancer of the male breast than in that of the female, but in the former the average survival is some eight months longer than in women, probably because in males the predominance of fibrous cancers is marked.

THE NEPHRITIS OF PNEUMONIA.

THE nephritis observed in pneumonia should be placed in the group of the infectious nephritides. As a distinctive character may be mentioned the fact that it is essentially hemorrhagic in type. It is met with in practice in two distinct forms, namely, (1) a pure nephritis without previous morbid changes in the kidney, and (2) associated with chronic renal lesions, usually of the interstitial type. The symptoms of pneumonic nephritis are due to an insufficiency of the urinary depuration; symptoms of uremia and consequently edema, dyspnea, albuminuria, delirium, or coma. The intensity and persistency of these symptoms, due to more profound morbid changes of the renal parenchyma, make the gravity of the associated nephritis. The prognosis of this nephritis is very bad. In 90 per cent. of the cases it is the cause of death in pneumonia, the gravity of which is in direct relation to the extent of the preexisting morbid changes in the kidney. Therefore, it is most essential at the onset of a pneumonia to elicit the pathological antecedents of the patient, to make a summary of his morbid history in order to form an estimate of the state of the kidneys and so to be able to formulate a prognosis. The age of the subject should enter largely as an important factor in the calculation of the probabilities.

But not infrequently the diagnosis of long-standing renal lesions is well-nigh impossible, either because the patient is not in a state to give the necessary data relating to his antecedents or to the objective and subjective symptoms which may have been present before the advent of the pneumonia, or because these symptoms may have been overlooked. Albuminuria as a diagnostic indication is most misleading, and from this fact the clinical prognosis of the pneumonia should in most cases be very guarded. Owing to the frequency of the interstitial lesions in serious cases of pneumonia and the uremic phenomena to which they give rise, and to the impossibility usually offered of making a diagnosis, the treatment to be adopted in all cases of pneumonia should be: (1) To avoid all causes which may influence the renal parenchyma in any manner; (2) To avoid those causes which might introduce a toxic principle into the organism which would become added to those already existent from the infection and the insufficiency of urinary depuration; (3) To facilitate the diuresis and the elimination of the toxic principles by all means at our disposal.

From this triple viewpoint one should therefore never resort to blisters, which irritate and cause congestion of the renal parenchyma and which decrease the daily output of urine when they do not cause anuria. Blisters can be replaced by derivatives and counterirritants quite as active and less dangerous, such as tincture of iodine or turpentine applied locally over the lung. As a general principle, all substances, the elimination of which by the kidney is difficult or which may increase the toxic principles in the organism, should be proscribed. And lastly, in serious cases in which the uremic phenomena of extreme intensity are a menace to the patient's life, blood-letting may be indicated, and with it injections of artificial serum.

ETIOLOGY OF PELLAGRA.

BABES in the *Bulletin de la Section Scientifique de l'Académie Roumaine* issued November 28, 1918, v, 6, and just received relates that in February of the same year the entire population of Bucharest was placed on a ration of bread made of maize and wheat flour. He had urgently advised that maize meal be strictly controlled but this was not heeded. Later he succeeded in getting samples of both whole maize and meal for analysis. The meal on the whole was inferior in quality, immature, and mouldy, while the grains were often in a state of germination. The meal had an unpleasant smell and bitter taste. The danger of an outbreak of pellagra was apparent to Babes and by the following May cases were in evidence. In June between the first and twenty-seventh days 34 cases of pellagra applied for treatment at the Coltza Hospital, the beginning of the affection going back to May and April. In the preceding year there had been no cases of pellagra in the city, and this is true of a number of past years. The public had not heretofore been compelled to eat maize and always preferred wheat bread when they could get it. The disease was mild in Bucharest, but in the provinces severe and fatal cases were seen, although formerly such severity was not so conspicuous. Before the present epoch the dis-

ease had appeared in Rumania only when the maize harvest was bad and much spoiled maize was eaten. The episode was instructive, Babes thought, because it seemed possible, by reason of the absence of the affection in recent years, to connect it with the spoiled maize diet and fix the period of incubation at two months. The earliest symptoms were joint pains, backache, general asthenia, heartburn, the characteristic burning and peeling erythema, and diarrhea. Treatment consisted in abolishing the maize diet and substituting one of eggs, milk, fats, cheese, meat, and vegetables.

Filtrable Virus.

To quote Laumonnier in the *Gazette des Hôpitaux* for February 10-12, 1920, xciii, 15, filtrable virus has acquired much notoriety since the influenza pandemic of 1918. We believed firmly in invisible bacteria for years before the discovery in thrush and the peripneumonia in cattle of germs so small that they passed through filters and could not be seen by the microscope. The filters referred to comprise those of Berkefeld, Chamberland, Kitasato, and others. This means that the bacteria do not measure more than 2 or 3 thousandths of a millimeter. The ultramicroscope cannot identify anything under 6 thousandths of a millimeter. Failure to recognize certain bacteria by the ordinary microscope always suggests that the right stain may not have been found. The distinction between filtrable bacteria and filtrable virus is readily made by heat, as the former succumb to a given temperature. The author enumerates nine affections of animals and twelve affections of mankind in which we may speak of filtrable virus, which for him is evidently tantamount to filtrable microorganisms, and this does not by any means exhaust the list. In some at least of these affections the filtrate of the blood of the infected subject is inoculable. In the peripneumonia of bovines positive cultural results have made the organism visible in cultures so that this organism is no longer included with the others. A point of interest is the pathogenicity of the unfiltered substance which in variola at least retains most of the virus. There are several transitions between filtrable and invisible and unfiltrable and visible bacteria—as in trench fever, hemorrhagic nephritis, and acute infectious polyneuritis, which are therefore not included in the above lists.

Can One Prepare an Alkaline Beerwort?

The Royal Society for Medical and Natural Sciences of Brussels has resumed its annual sessions and the first report has recently been published. The chief paper, by Kufferath, bears the above title, the interest being scientific rather than industrial. Beer yeast is believed to be normally acid and this acidity enables the alcoholic ferments to act in the presence of bacteria and molds. The *Saccharomyces* does not thrive in an alkaline medium, because of the rapid proliferation in such medium of other organisms. It might become possible to form alkaline yeast if the growth of these organisms could be inhibited or if some preferred culture medium could be devised. The author, whose article appears in the *Annales et Bulletin de la Société Royale des Sciences Médicales et Naturelles de Bruxelles*, 1920, No. 1, made studies of a beer which he first sterilized for 15 minutes at 120°C. Its acidity was found to be 7.6 per 100. Alkali was added in various proportions. It was found to be very difficult to obtain an alkaline yeast and impossible if the yeast was heated. In the cold and with concentrated lye a yeast profoundly modified was obtained. Neutral yeast on the other hand was practicable and the reaction did not change the characters. In order to study the effects of cultures with alkalinized yeast a hydrolyzed starch was used. After one week ordinary acid yeast produced a given amount of CO_2 from a given amount of substratum, while neutral yeast produced nearly as much, but yeast ten times alkalinized produced only a small amount and one twenty fold alkaline none at all. One yeast germ, the *Torula laurentii*, was able to proliferate in a 20-fold alkaline medium, but none of the others tested could grow at all in this concentration. The author appears to have shown that yeast can grow in alkaline media and cause normal fermentation.

Vincent's Angina Simulating Chancre of the Tonsil.

This error in diagnosis is occasionally made and Cornaz reports an example in the *Revue médicale de la Suisse romande* for December, 1919, xxxix, 12. The patient, aged 26, presented himself with the statement that he had contracted a disease from a woman. An ulcer the size of a five-franc piece was to be seen on the internal aspect of the right cheek, with an infiltrated base, sanious discharge, and swelling of the regional lymphnodes. This lesion yielded promptly to iodine tincture and hydrogen peroxide. About three weeks later the patient reappeared with a similar lesion on the right tonsil and was sent to the hospital. The simulation of tonsillar chancre was absolute, although there was but little dysphagia. The adenopathy was indolorous. The patient had been exposed to venereal contagion six weeks before as admitted when he first sought treatment. However the ultramicrosope showed no treponemata but instead the spirochetes and bacilli of Vincent's disease. The Wassermann test was negative. Salvarsan, being indicated alike in both syphilis and Vincent's disease, was injected intravenously and great improvement was evident the following day, while five days later there was no trace of the lesion. In this case the presence of the earlier lesion of the cheek would have been sufficient to throw some doubt on the diagnosis of chancre. Fournier in his great work of extragenital chancre devotes considerable space to the type which simulates Vincent's disease and lays stress on the fact that a chancre in the tonsillar region cannot be properly palpated so that the typical induration of the base can neither be affirmed nor denied. In chancre of the throat of this type there is a marked local and constitutional reaction with considerable fever, intense dysphagia, and sensitive enlarged lymph nodes. In the present case there was no fever, and but little discomfort on swallowing, while the engorged glands were but slightly sensitive.

News of the Week.

Vocational Training for Industrial Cripples.—The Senate bill providing for the vocational training of persons crippled in industry was passed by the House of Representatives and sent to the President on May 25. Under this bill the Federal Government and the States would share the cost. The State authorities would have direct charge of the work under Federal supervision.

All Passaic Children to Be Vaccinated.—Owing to the fact that the physical director of the public schools of Passaic, N. J., was recently found to have smallpox, the Board of Education has ordered the immediate vaccination of the ten thousand children in the public schools of that city. Teachers are not to be exempted. It is expected that this order will arouse a war between the parents on one side and the Board of Education, and the Department of Health on the other, as a number of parents have declared that they will refuse to obey the order.

A Town Without a Death in Fifty-seven Years.—Carnmore, Cal., boasts of being the healthiest community in the State, there having been no death in the town since 1863, when the last funeral was recorded.

New York Association for Medical Education Issues Bulletin.—This organization having for its purpose the expansion of medical education in this country and the utilization of the vast amount of clinical material afforded by the hospitals and clinics of Greater New York, has issued its first Bulletin. This consists in a report of the Subcommittee on Ophthalmology and Otolaryngology, of which Dr. James F. MacKernon is chairman, and Dr. Arnold Knapp, Dr. Cornelius G. Coakley, and Dr. Frederick Whiting are members, formulating the requirements necessary to educate and train physicians who desire to become specialists in the department of Ophthalmology, Rhinolaryngology and Otology. All the details of a standard course and of graduate courses of instruction are outlined and are now available. Those interested can obtain further information at the headquarters of the association—17 West Forty-third Street, New York.

Physicians Advance Fees.—The physicians of New Bedford, Mass., announce that they have found it necessary to advance their fees and have adopted a new scale of prices which places the maximum fee for calls at $4 for a day visit, $7 for a night visit, and $10 for a consultation. They state, however, that where it would be an injustice to charge the maximum fee, the circumstances of the patient, as heretofore, will serve as the basis.

New Diabetic Clinic for New York.—Dr. Thomas W. Edgar, who has been conducting a free clinic for diabetes patients at 766 West End Avenue, has leased the three-story dwelling at 439 West Twenty-first Street, where he will open a new clinic in September. This clinic has been endowed by W. H. Jordan, and a fund left recently by the late Henrietta D. Burrows has made possible the purchase of larger quarters.

Typhus Suspect on Liner.—The Italian steamship *Guiseppe Verdi*, arriving in New York from Naples on May 27, had among its 2000 steerage passengers a case presenting symptoms of typhus fever. The liner was held in quarantine and the occupants of the steerage were sent to Hoffman Island for observation.

New York Post-Graduate Extends Campaign.—The campaign to raise $2,000,000 for the New York Post-Graduate Medical School and Hospital will be carried on through the summer. The fund, on May 28, totaled $1,277,176.57.

Amendment to New York Labor Law.—One of the amendments to the Labor law, passed by the New York Legislature at its recent session, provides that after July 1, 1920, children between 14 and 16 years of age employed in mercantile establishments shall be subject to physical examinatinos of the same kind required in the case of children working in factories. These examinations are to be made by medical inspectors on the staff of the State Industrial Commission.

To Deport Alien Insane.—The United States Bureau of Immigration is planning to send back to Europe some 6,000 alien insane patients in the institutions of this country. Of this number there are some 800 in the New York State Hospitals who will probably be returned to their home countries. This will greatly relieve the present congestion in the New York institutions.

Dr. Julius Jerome Goldstein of this city, whose death was reported several weeks ago, is, we are most happy to state, very much alive and busily engaged in averting death from others.

Mary Putnam Jacobi Fellowship.—The Mary Putnam Jacobi Fellowship for 1920-1921 has been awarded to Dr. Sophie Getzowa, University of Berne, Berne, Switzerland.

Dr. D. Edmund Smith of Minneapolis has received his second decoration from the French Government, the Médaille de Reconnaissance Française, in recognition of services rendered at Lourdes, France, where he established a sixty-bed hospital for the care of refugees from the devastated areas, and for his services in caring for children who had lost their parents in the battle area.

Dr. John F. O'Brien of New Haven, Conn., has been appointed superintendent of the Seaside and Crescent Beach Sanatorium, a new institution for the care of children suffering with bone and glandular tuberculosis.

Gifts and Bequests.—Under the will of Henry C. Kelsey, formerly Secretary of the State of New Jersey, the Mercer Hospital, Trenton, N. J., receives a bequest of $50,000 and the McKinley and St. Francis hospitals receive $80,000 each.

The Servants for the Relief of Incurable Cancer, New York, have received a bequest of $1,000 under the will of John Joseph Scott.

Position Open for Bacteriologist and Pathologist.—The Civil Service Commission of the State of New York announces an examination on June 19, 1920, for the position of Laboratory Assistant in Bacteriology, State Department of Health, at $720 a year. Applicants must have had a college education and a complete course in bacteriology. The position is open to residents and non-residents and citizens and non-citizens.

A competitive examination for the position of Assistant in Pathology, State Institution for the Study of Malignant Disease, Buffalo, N. Y., at a salary of $1,800 is also announced for June 19, 1920. Applicants for this position must be graduates of

a Class A medical school, and it is desired to secure an appointee who has served a term as interne in a recognized hospital or who has completed post-graduate work in a pathological or bacteriological laboratory. Applications for forms must be sent to the Civil Service Commission, Albany, N. Y., before June 7. Those received after June 9 may not be accepted.

Health Organization Offers Fellowship.—The Child Health Organization of America offers a fellowship of one year in Teachers' College, Columbia University, for the study of modern health education in the elementary schools, to be awarded for the best graded plan and outline for interesting children in the establishment of health habits. Details will be furnished on application to the Child Health Organization of America, 156 Fifth Avenue, New York.

Health Department Finds Many Clinical Thermometers Inaccurate.—The Sanitary Bureau of the New York City Department of Health has made a survey of a number of clinical thermometer factories in and out of the city and has submitted a report of methods used by these concerns. To demonstrate to physicians and nurses the worthlessness of some of the thermometers upon which they have been depending, a testing outfit was obtained and competent men have tested 156 thermometers obtained from doctors and nurses. As a result of the test 84, or 54 per cent., of these thermometers were found defective, while 72, or 46 per cent., were found acceptable. As the thermometers had to be returned within a few hours repeated readings could not be taken, and all the tests to determine the accuracy of thermometers were not carried out in full. It is probable that some of the thermometers passed would prove defective were they subjected to all the tests. As a result of the knowledge obtained through this survey the Board of Health has under consideration an appropriate amendment to the Sanitary Code and regulations to govern the selling, holding, or keeping for sale of clinical thermometers in this city.

Medical Society Elections.—The Bristol South District Medical Society, at its annual meeting held in New Bedford May 6, 1920, elected the following officers for the ensuing year: *President*, Dr. E. P. Gardner; *Vice-President*, Dr. A. I. Connell; *Secretary* and *Treasurer*, Dr. A. J. Abbee.

THE FRANKLIN DISTRICT MEDICAL SOCIETY, at its annual meeting in Greenfield, Mass., May 11, elected the following officers for the ensuing year: *President*, Dr. John Mather; *Vice-President*, Dr. E. C. Thorn, Deerfield; *Secretary* and *Treasurer*, Dr. F. A. Millett.

THE NORFOLK (MASS.) DISTRICT MEDICAL SOCIETY, at its annual meeting held May 13, elected the following officers for the ensuing year: *President*, Dr. G. W. Winchester, Mattapan; *Vice-President*, Dr. C. W. Knowlton, Roxbury; *Secretary*, Dr. Bradford Kent, Dorchester; *Treasurer*, Dr. G. W. Kaan, Brookline.

THE WILLIMANTIC CITY MEDICAL SOCIETY, at its annual meeting held in Norwich, Conn., May 3, 1920, elected the following officers for the ensuing year: *President*, Dr. John Welden; *Vice-President*, Dr. William E. Hendry; *Secretary* and *Treasurer*, Dr. Michael D. Riordan.

THE KANSAS STATE MEDICAL SOCIETY, at its annual meeting held in Hutchinson May 6, elected the following officers for the ensuing year: *President*, Dr. C. Kippel, Hutchinson; *Vice-Presidents*, Dr. J. R. Scott, Ottawa; Dr. J. L. Everhardy, Leavenworth; Dr. Herbert Randels, White City; *Secretary*, F. J. Hasig, Kansas City; *Treasurer*, Dr. L. H Munn, Topeka.

THE MEDICAL SOCIETY OF THE STATE OF CALIFORNIA, at its annual meeting in Santa Barbara, May 13, 1920, elected the following officers for the ensuing year: *President*, Dr. John H. Graves, San Francisco; *First Vice-President*, Dr. William Duffield, Los Angeles; *Second Vice-President*, Dr. Joseph Catton; *Secretary and Treasurer*, Dr. Saxton Temple Pope.

THE BROCKTON (MASS.) MEDICAL SOCIETY, at its annual meeting held May 13, 1920, elected the following officers for the ensuing year: *President*, Dr. George A. Buckley, Brockton; *Vice-President*, Dr. Walter V. Vannerman, East Bridgewater; *Secretary*, Dr. P. H. Leavitt; Treasurer, Dr. J. A. Pettey, Brockton.

THE NEW HAMPSHIRE STATE MEDICAL SOCIETY, at its annual meeting held in Concord May 13, 1920, elected the following officers for the ensuing year: *President*, Dr. A. H. Harriman, Laconia; *Vice-President*, Dr. Charles S. Walker, Keene; *Secretary-Treasurer*, Dr. D. E. Sullivan, Concord.

THE SALEM (OHIO) PHYSICIANS' CLUB was organized on May 13, at which time the following officers were elected for the ensuing year: *President*, Dr. F. T. Miles; *Vice-President*, Dr. A. W. Schiller; *Secretary and Treasurer*, Dr. T. T. Church.

THE SOUTHERN OREGON MEDICAL ASSOCIATION, at its twenty-ninth annual session held in Roseburg, May 13, 1920, elected the following officers for the ensuing year: *President*, Dr. L. O. Clement, Grants Pass; *Vice-President*, Dr. E. B. Pickel, Medford; *Secretary and Treasurer*, Dr. A. C. Seely, Roseburg.

Obituary Notes.—Dr. HENRY J. ALLEN of Corinth, N. Y., a graduate of the University of Vermont College of Medicine, died suddenly at his home, on May 26, aged 71 years.

Dr. ISAAC IRWIN KALBACH of Glen Riddle, Delaware County, Pa., died at Taylor Hospital, Ridley, on March 13 of apoplexy at the age of 56 years. He was graduated from Jefferson Medical College in the class of 1893.

Dr. CARL KIRSCHNER, formerly of Philadelphia, died at Erie, Pa., on April 20 at the age of 41 years. He was graduated from the Medico-Chirurgical College in the class of 1903.

Dr. WALTER G. SPIESS died of nephritis at Philadelphia on April 23 at the age of 40 years. He was graduated from the Medico-Chirurgical College in the class of 1903. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. FERDINAND SIEGEL, a graduate of New York University Medical College, in 1890, died at his home in Brooklyn, N. Y., on April 25, aged 53 years. He was chief of the general medical staff of the Bedford Maternity Hospital and pediatrician to the Bedford Dispensary.

Dr. JOSEPH LANDER SANBORN, a graduate of the

Atlanta Medical School, in 1894, died at his home in North Amherst, Mass., on May 17, at the age of 54 years.

Dr. VALENTINE WINTERS ANDERSON, a graduate of Louisville National Medical College, in 1900, died at his home in Dayton, Ohio, May 10. He was born in 1871.

Dr. RUFUS E. DONNELL, a graduate of Dartmouth Medical College, in 1888, and for several years a member of the City Council of Augusta, Me., died at his home in that city, on May 16, aged 61 years.

Dr. HARRY A. COSLER, a graduate of the Columbus (Ohio) School of Medicine, in 1902, died at his home in Fairfield, Ohio, on May 13, at the age of 47 years.

Correspondence.

THE LATE DR. JOSEPH FRAENKEL.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The character and career of the late Dr. Joseph Fraenkel deserve more than ordinary comment and appraisal. They have received little or none. Yet not long ago and for a good many years he had a commanding practice among the most intelligent and wealthy members of this New York community. His success in diagnosis and treatment, his quiet efficiency in securing results, his acuteness of observation and his complete confidence in his methods, impressed his patients and they held him in an almost God-like reverence.

For a good many years Dr. Fraenkel was an associate of mine in dispensary, hospital, and teaching work, and I held him as one of my choicest friends. His social qualities were compelling and unique. He was full of enthusiasms which he clothed with picturesque language and endowed with humor and eloquence. He loved music and literature and art, and at a dinner table was an unfailing stimulus to a joyous and esoteric conviviality.

He was a very thoroughly educated and broadly trained physician. In the early years of the Montefiore Home he gave much help to the organization and development of the neurological and general medical work.

As associate professor of Neurology at Cornell I knew he could teach and interest students better than myself and I lamented his withdrawal. He must be given merit as of the band which organized the New York Neurological Hospital.

In his later years, after he left the Neurological Hospital, he pursued an extraordinary and successful career as a neuroendocrinologist and more especially as a therapeutic individualist. What he accomplished, what he knew, how far his methods were psychical and suggestive, how far they were pharmacological, I do not know. I hope someone can tell us. He was believed to achieve dramatic and notable results by very unusual methods. Whether he did or not, his character was to me always that of a sincere, honest and lovable and loyal man. I lament his loss; and I hope there will some time be written a competent story of his life. There has been no career quite like his in the history of the New York profession of medicine.

CHARLES L. DANA.

NEW YORK.

PLASTIC CONICAL ENUCLEATION OF THE CERVIX UTERI.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In a paper entitled "The Treatment of the Infections of the Uterus and Cervix—Preliminary Report of 75 Cases" (MEDICAL RECORD, June 28, 1919), the writer, after a brief description of an operative method for removing completely the diseased cervical mucosa and relining the cervical canal with a cylindrical flap of mucosa obtained from the vaginal surface of the cervix, says: "I have named this operation 'Plastic Conical Enucleation of the Cervix.' So far as I know, this is the first clinical report covering a series of cases operated upon by this method. To Dr. Arnold Sturmdorf (Sturmdorf: Tracheloplastic Methods and Results, *Surg. Gyn. and Obst.*, Jan., 1916, pp. 93, 104; Chronic Endocervicitis, Transactions of the Soc. on Obst., Gyn. and Abd. Surg. of the A. M. A., 1917, pp. 42-53) belongs the credit of first describing the operation and of working out the pathology of cervical infections, and I wish to express my appreciation of his highly valued help and suggestions during the time that I had the pleasure of being associated with him at the Polyclinic Hospital." The writer thought that this did, and fully intended that it should give Dr. Sturmdorf full credit for inventing this operation. But it has just been called to his attention that the sentence does not convey the idea that he wishes to make plain, *i.e.* that Dr. Arnold Sturmdorf invented and first described this operation. The writer wishes therefore to alter this sentence to read: "To Dr. Arnold Sturmdorf belongs the credit of inventing and first describing the operation," etc.; and he wishes this correction to apply to any later article of his upon this subject.

FRANCIS WARD LANGSTROTH, M.D.

NEW YORK.

SOME SO-CALLED ADVANCES IN THE PRACTICE OF MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—To not a few men to-day, who are good and busy practitioners, medical societies and associations are rapidly losing interest. By attending these meetings, often at the cost of valuable time, or when they could be taking well earned recreation, they learn practically what is of very little or no value in caring for their ill and suffering patients. Too often they listen to half-boiled researches on the part of young men who have had little real experience in taking care of patients, and what they do know is all hospital findings and doings. Their final appeal is too often to laboratory work, much of which is very new and still unsubstantiated by actually sufficient results to increase faith among their elders who have "borne the burden and heat of the day" and who really know what is useful and desirable and what is not, or in any event, what is of very doubtful value. Again, is the new, so-called advance, which we now have in our cities and in some of our best hospitals—notably the Massachusetts General Hospital of Boston, Mass., in sustaining and strongly advocating diagnostic clinics, where the difficult cases can go, be examined by different prominent specialists for a relatively small amount

of money, and later returned to their former medical advisers, probably their family physicians, with the diagnosis and maybe the treatment affirmed, or as it were, definitely established; is this really to be considered advantageous? In some cases, perhaps, it is. In many instances, assuredly it is not.

My observations would go to show that very refined diagnoses are of decidedly greater interest to the research worker than they are to the all-around practitioner or, in final outcome, to the patient.

The sooner we appreciate thoroughly that we do not, as a rule, cure disease the better. What we do is to relieve symptoms and do it, so far as possible, without doing notable harm.

To me it is lamentable and deplorable in the highest degree the way in which the old and better treatment of ordinary ailments has passed by and is now absolutely ignored or neglected. True, we have had some great and notable discoveries in the practice of medicine during the past twenty or thirty years, but they can be counted on one's fingers. And the modern way of making every man, woman, and child introspective and searching for or recognizing ailments, serves no good purpose. It lessens faith in one's sanest adviser and bandies the poor, misguided victim of so-called science from one physician's control to another's.

Thus it is that the latest outpouring of a city doctor of wide experience is that he is ashamed to take people's money for the treatment of an ordinary cold, because he knows how useless his advice is. If we simply went back to the good old days of nitre and ammonia and backed it up with a mustard foot bath and hot toddy, there would be little or no call for poisonous aspirin and still more abominable acetanilid, which has brought death to many.

BEVERLEY ROBINSON, M.D.

42 WEST THIRTY-SEVENTH STREET.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, May 7, 1920.

Midwifery Training.—It is beginning to be understood that reform in the practise of midwifery and in the training of midwives must be inaugurated at once in Great Britain. A national scheme is in process of formation. There are few people probably in this country who realize how limited the opportunities are for training in midwifery, or, as Miss Gregory, daughter of the late Dean of St. Paul's Cathedral, states, "Our standard is the lowest in Europe." Miss Gregory is somewhat of an authority on the subject, for she started the British Hospital for Mothers and Babies at Woolwich, and besides she has had a wide experience as a district midwife working in the homes of the poor. After the hospital had taken definite shape by 1915 the Charity Commissioners had approved a scheme under which the valuable site of that institution could be sold. In the interval the Council for the Promotion of the Higher Training of Midwives had kept its own aims steadily in view. One therefore became the complement of the other, and Woolwich, it may be said, offered special claims to consideration as the center of the joint work. In the first instance, it presented a large population of workers, dockyard, arsenal, and industrial, who needed a modern maternity hospital in their midst. The proximity to London was a recommendation for many obvious reasons to intending students, who recognized the fact that between the cases within the hospital wards and those attended in the mothers' own homes they would obtain the varied experience essential for complete comprehension of the subject.

The necessary land on which to build was acquired and an appeal has just been launched for one million shillings, which when contributed will render it possible to take up a work for which the need is urgent and imperative. The real crux of the problem is the difficulty of finding women qualified by knowledge and experience who are capable of imparting instruction to others. Of course, it is a field of nursing that calls for special attributes; but hitherto, a six months' course—previously it was not longer than three—has been held to be sufficient time in which to acquire the skill and scientific knowledge that should be possessed. As one authority has said: "Six months in which to teach the elements of anatomy and physiology, and many of the candidates now presenting themselves hardly know the difference between a vein and an artery, and cannot tell one bone from another; to master the intricate technique of antiseptics; the details and care of normal labor, and when by small and insidious approaches the abnormal is beginning to show itself."

The point of view taken up at the British Hospital for Women and Babies is that every school for training these women requires teachers able to impart what they have themselves learned. It further recognizes that such teachers must have had the advantages of a modern and fully supplied professional library. When such teaching has been efficient there is no question as to the results that follow. New Zealand supplies the most conspicuous object lesson. At Woolwich, if the entire scheme is realized, there will be forty-two beds for mothers. The staff will consist of forty nurses and pupils, and it is estimated that 650 women will pass through the wards during the year, while quite 1000 cases will be attended in their own homes. Accordingly the opportunities for observation and the possibilities of seeing difficult midwifery will be large. Those students who have had general training in hospital nursing will remain for a year's course if intending to take up district work, or for two years if desirous of preparing themselves as teachers of others. Proceeding along these lines it is hoped to attract a class of women better educated and with higher ambitions than that which has formerly taken up the work. The British Government has set up a standard of knowledge and those who wished to enter the calling had to pass a by no means easy examination. Having, however, obtained the certificate of the Central Midwives' Board the holder had no certainty whatever as to what her earnings might be. In country districts these were often of a pitifully low nature. It may be stated that in this latter respect there has been decided improvement in the past two years. Both in the coun-

try and in London and other large towns the certified women have been able to raise their fees and to secure a scale of remuneration more in keeping with the skill and aid that their knowledge brings to the service of their patients. Associated with the financial side of the enterprise is Lieut.-Col. Sir Richard Temple, who did so much good work for the Joint Committee of the British Red Cross and Order of St. John. He is addressing himself to the interests of men in this question, and has been pointing out to them the loss to the nation of the 40,000 women who die or are physically disabled annually through ignorant and incompetent treatment, and the 100,000 valuable infant lives thrown away for the same reasons in the first twelve months of their existence. To avert such useless waste is, he says, the tribute that every chivalrous, right feeling man owes to womankind, and he bids them remember that everyone who faces the bringing up of a new little life into the world goes figuratively over the top. Sir George Newman, the chief medical adviser to the Ministry of Health, in the work, "The Outlines of Preventive Medicine," lays great stress on the need for thorough and immediate reforms in the practice of midwifery and in the training of medical students and midwives in that branch of medicine and surgery. The British Hospital for Women and Babies is a step forward and one which should be imitated in every part of the country.

New Institute of Physics.—As the *Times* of May 5 points out, the need has long been felt for a corporate body analogous to the Institute of Chemistry, which would represent the profession and strengthen the position of workers engaged in physics, and which would also form a bond between the various societies interested. At present the physicist is hardly recognized as a member of one of the professions, but the vital importance of many developments of physics during the war and the certainty of its growing importance both in science and industry are bringing about a change in this respect. It will be one of the aims of the new Institute of Physics to secure recognition of the position and value of the physicist and it is felt that such recognition can only be obtained by the cooperative action of all the physicists in the country. The institute has been founded, in the first instance, by the cooperation of the Faraday Society, the Optical Society and the Physical Society of London, and the first board is constituted from representatives appointed by the councils of these societies. It is hoped that in the course of time other societies will associate themselves with the institute. Members of the institute who are also members of more than one of the cooperating societies will obtain a reduction in the subscription to those societies. There will be three classes of members: ordinary members, associates, and fellows Only the two latter classes, membership of which will require full professional qualifications, will be corporate members.

The institute has already received promises of support from leading physicists and the initial expenses are covered by a guarantee fund amounting to over £1,200. The first president of the institute is Sir Richard Glazebrooke, F.R.S.; Sir Robert Hadfield, F.R.S., is treasurer, and Professor A. W. Porter, F.R.S., honorary secretary.

A Nerve Ridden Queen.—Long-held views are being constantly overthrown and the other day several conventional ideas with regard to Queen Elizabeth were disturbed by Dr. Frederick Chamberlin, F.R.H.S., the American historian, who lectured on Queen Bess at the Royal Institution on May 1. In this and in a second lecture Dr. Chamberlin is endeavoring to summarize the results of years of research, and at the outset he noted the astonishing fact that only one really full life has been written of the Queen, who, as he stated, "founded Great Britain, and was its last and its greatest monarch." Dr. Chamberlin said that when he undertook his research he held the ordinary conventional ideas of Elizabeth and believed that she had been too intimate with those whom we dubbed her "favorites," for such substantially was the opinion of the average man and of all women. Such, too, was the teaching of all historians. The lecturer quoted the description given of Elizabeth in the "Dictionary of National Biography," and stated he believed it to be demonstrable that the true description would have been in the following paraphrase: "In person Elizabeth could never have been a beautiful young woman. She was emphatically her father's child. From him she derived her great lack of physical vigor, her sickly constitution, a frame incapable of bearing fatigue, and a nervous system that rendered her extremely sensitive to fear or pain. Her life was the life of a woman, not of a man. She could never hunt, dance, or do anything calling for physical exercise without collapsing as a consequence, and she always seemed to suffer from the tension at which she lived. She never enjoyed good health after she reached her fourteenth year." Dr. Chamberlin based these statements on written opinions of eminent medical experts, including the late Sir Wm. Osler, Sir Clifford Allbutt, and Professors Keith and Doran. He had submitted to them a statement of the records of the illness of Elizabeth for her entire life, and they had unanimously agreed that she was never physically strong after the age of fourteen. For a whole decade before she came to the throne she was afflicted by continuous attacks of some disease from which she never seemed to have recovered. She suffered from frequent nervous attacks, or fits, with habitual melancholia, and periodical attacks of unconsciousness which lasted for many hours. She was always very thin, except when attacked by dropsy, from which she was sometimes so swollen as to be unrecognizable. She had the instincts neither of a sweetheart nor of a mother, which would have been impossible in a frame such as hers. Her condition was really sexless. "She toyed with young men, but one cannot conceive more than that," said the lecturer. "Her condition freed her from the bonds which bind most women, but in exchange she had to bear other bonds, the misery of disturbed health and ill-being. If a study of Elizabeth's health and illnesses can throw a light on her character, and through her on the history of her period, it will be found in the disordered condition of her

sexless system. It is this frail anemic, weak, sexless woman, with no capacity for feeling natural sex desires, with no yearning for motherhood, to which study will be directed in the next lecture. Her memory, her fame, her pride, her right, and her helplessness against the innuendoes of the jealous, the disappointed, the idle, and the gossip, demand an unbiased test of all the evidence which is now available for the first time. Elizabeth could and would demand no more." Although Dr. Chamberlin does not refer to it in his first lecture, it may well have been the syphilitic condition of Henry the Eighth that was mainly responsible for his daughter's ill health. It seems to be generally accepted as an historical fact that Henry VIII was diseased with syphilis, and if this were so it would account to a great extent for the state of health of his daughter Elizabeth.

4. A Case Showing Apparent Paradoxical Respiratory Arrhythmia of the Heart.—Paul D. White cites the case of a young man, twenty-three years of age, whose auricular and ventricular rates were from 40 to 43 when he was quiet in bed. During deep inspiration the auricular rate increased to 70 and the ventricular rate fell to 35. During deep expiration the auricular and ventricular rates were both 41. Immediately after moderate exertion the auricular rate was 72 and the ventricular rate 36. Ordinarily one finds an increase in heart rate with inspiration and exercise; in this instance there was a decrease. This paradoxical condition is due to the occurrence of two to one heart block when the auricular rate rises above a certain point. It seems evident that the auriculo-ventricular tissue is depressed, probably by disease in early childhood, so that beyond a certain point it fails to transmit every other auricular impulse. Atropine produced a ventricular slowing in this case.

2. The Reeducation of Hemiplegics and Their Physiotherapeutic Treatment.—Pierre Kouindjy gives statistics gathered at Saltpêtrière during the past five years showing the results of methodical massage and motor reeducation in hemiplegics. In three per cent. of the cases complete cures were obtained; in 17.7 per cent. great benefit was derived; in 64.7 per cent. a notable benefit, and in 17 per cent. the result was doubtful. The treatment should be begun early and only hypotonic muscles massaged. When these muscles are capable of standing more vigorous treatment, mechanical percussions and other measures are added, consisting in a series of simple appliances. In explaining the action of motor reeducation the writer states that if the exercises do not succeed in restoring the cerebral centers they may have the effect of supplanting them. In residual hemiplegia it is almost certain that motor reeducation creates supplementary centers and these may have the effect of supplanting the original centers of coordination. Heliotherapy, thermotherapy, and balneotherapy are useful adjuvants.

4. The Etiology of Neurotic Symptoms in a Child of Eight.—Adolph Stern reports this case because he finds wishes, some conscious, others not, which are identical with or very similar to those which we find in the unconscious of the adult. The findings in this child furnish added proof, if any is still needed, to demonstrate the accuracy of the deductions made by psychoanalysis as to the causal relation between unconscious mental processes and neurotic symptoms, and also that what we call the unconscious in the adult had its origin in the child, and is in the child quite conscious before the period of repression sets in. The case also furnishes points of interest in regard to the relative value of heredity and environment in the causation of symptoms in the neurotic constitution. The writer shows how the neurotic constitution may be formed so early in the life of the individual, owing to the fact that parents or those in the immediate environment, show neurotic manifestations, that one may be led astray and ascribe it to an hereditary origin. What are inherited, so far as the emotions are concerned, are the primary emotions that accompany the instincts. The neurotic constitution may perhaps be viewed as a secondary characteristic, and as such generally recognized as an environmental attribute rather than an hereditary one. In this sense all individuals are neurotically inclined. The early environment has much to do in deciding the manner of reaction of the individual to these primary emotions, and what enters into this decision one may view as factors forming a neurotic constitution in case these factors tend in that direction. This the writer considers an important field, which will yield much information that can be used from a therapeutic point of view with great benefit.

3. Anthrax: Comparison of Surgical and Nonsurgical Methods of Treatment.—Albert J. Scholl reviews 51 cases of anthrax treated at the Massachusetts General Hospital between 1888 and 1918, of which seven died, a mortality of 17.7 per cent. The early diagnosis was made bacteriologically by the demonstration of the anthrax bacilli in the wound in 81.2 per cent. of the cases. Four of nine patients, or 44 per cent., treated surgically died; only 3, or 7 per cent., treated nonsurgically died. Forty-two patients had lesions on the face and neck. Cervical infections are especially dangerous, two of the patients treated nonsurgically died from respiratory difficulty resulting from the associated edema. The patients treated nonsurgically were confined to bed. Their lesions were left absolutely alone and exposed to the air; no special general measures were carried out. In several surgical cases a rapid increase in the edema, a steady decline in the patient's general condition, and death several hours later pointed to the operation as the causative factor.

5. Incidence of Tuberculosis in Husband and Wife.—Arnold Minnig has investigated 1,000 successive dispensary cases, being careful to classify none as tuberculous which were in the least doubtful. In this series 502 patients were married, and there was active tuberculosis in husband and wife in 44 cases, or 8.7 per cent. When a consort died, the mate was infected in 50 per cent. of the cases. He concludes that there is

such a thing as adult infection and that the physician should constantly bear this in mind in his advice to laymen. It is evident that when there is a continued massive infection over a period of years, and especially when the consort dies, since in these last years the patient is especially careless and slovenly, there is not only a possibility of contagion, but in one out of every two cases active tuberculosis supervenes. The writer's investigation covered only dispensary cases. In private practice the incidence of marital infection is smaller, proving that intelligent prophylaxis is worth while.

6. Calculi in the Salivary Ducts.—Seward Erdman points out that unless the possibility of this condition is borne in mind, and a careful diagnosis made, there will be numerous instances in which a totally unnecessary operation will be performed without relief of the symptoms. In some of these cases an alveolar abscess may be suspected, while the acute cases are likely to be diagnosed as cases of suppurative lymphadenitis, and treated by external incision. In the cases of chronic enlargement of the gland malignancy may be suggested. Examination of the floor of the mouth or cheek will usually show some change at the exit of the duct, a purulent discharge or swelling and redness. In the writer's experience with Wharton's duct, the stone is likely to be found rather far back, about opposite the last molar tooth. The treatment consists of one of two methods: After the application of local anesthesia in the vicinity of the duct, a probe is inserted and the duct split back as far as may be necessary to deliver the calculus, which may require a spoon curet, or a direct incision may be made through the mucous membrane and into the duct at the site of the previously located stone, or into the distended duct behind the stone. External incisions are seldom if ever indicated.

2. The Pellagra Outbreak in Egypt. 1. Pellegra Among the Ottoman Prisoners of War.—A. Douglas Bigland describes the characteristics of the disease as it manifested itself during this outbreak. In addition to the skin and gastrointestinal troubles there were great weakness and emaciation, together with nervous symptoms. An acute type of the disease is recognized to which the term typhoid pellagra is applied. The writer mentions one condition to which only one reference could be found in the literature, and that was that in eight cases of the 64 cases studied there was noted a seborrheic condition, chiefly around the alae nasi, sometimes scattered over the whole face. This condition was not found among non-pellagrous Turks. Autopsy was performed on 24 of 26 cases that died. The intestines showed the usual changes associated with bacillary dysentery, while the other organs appeared for the most part normal. Microscopic sections of all organs except the brain and spinal cord were examined. The writer holds that pellagra is not necessarily a clinical entity. It may be rather of the nature of a syndrome, for which more than one factor may be responsible. There is also extreme variability in the severity of the disease. Three grades are recognized: Grade I is exemplified by a small Egyptian gardener boy who developed pellagra and was cured almost immediately by adding one egg per diem to his diet. Grade II is present when the pellagrin can be saved only by relentless feeding. Grade III is the stage in which the balance is lost entirely and nothing can reestablish it, as in the young diabetic. There is evidence that pellagra is a syndrome which occurs most often in the underfed, using that expression in its scientific sense, though it may occur in the well fed. In the latter class of cases it is suggested that a toxin is present which acts upon the intestines and the contents thereof in such a way that protein is not assimilated as it should be. The writer discusses the nature of this hypothetical toxic substance.

3. Intracardiac Pressure as a Standard in Cardiotherapy.—I. Harris has attempted to develop a standard by which the degree of abnormality in the cardiac mechanism can be gauged, and to prove that the intracardiac pressure supplies such a standard, not only for diagnostic, but for therapeutic purposes. He proposes the estimation of intracardiac pressure by ascertaining the duration of the diastole in relation to the systole by means of the electrocardiogram, and thinks we may safely assume, everything being equal, that the strain which the heart muscle has to bear during its systole will be proportionate to the length of the diastole. It is possible to some extent to supplement the data derived from the duration of the diastole in regard to the intracardiac pressure by measuring the pulse pressure. Two factors are concerned in the production of heart failure: the condition of the heart muscle, and the intracardiac pressure. A moderate intracardiac pressure acting on a damaged heart might suffice to produce heart failure. An abnormally high intracardiac pressure acting on a healthy muscle should, theoretically, at any rate, also be able to induce heart failure. Two types of heart failure are described, the most striking feature of one type being the normal condition of the arteries and peripheral circulatory apparatus in general, while the second type is associated with arteriosclerosis and the clinical features are totally different from the foregoing one. Digitalis is clearly indicated in the first type of heart failure and the exact dosage can be regulated by taking as guide the state of intracardiac pressure. In cases showing the second type of heart failure digitalis is not indicated. Any drug which would increase the intracardiac pressure would only aggravate matters. The ideal treatment in such cases would be the one which would lower the intracardiac pressure and at the same time leave the arterial pressure unaltered. The prolonged use of nitrites is contraindicated in such cases because they lower the arterial pressure. Caffeine seems to have all the properties for the treatment of such cases. It is sometimes a good plan to treat the patient alternately with caffeine and atropine. As soon as the pulse rate is considerably increased the intracardiac pressure falls proportionately. Small doses of digitalis are then useful, and may be continued until there is evidence of a considerable rise in intracardiac pressure. The treatment of edema by digitalis in these cases is contraindicated, while adrenalin has been found most useful for this purpose.

1. Lecture on Bronchiectasis.—A. J. Jex-Blake bases this lecture on the clinical notes and post-mortem records of over 100 cases of bronchiectasis at Brompton and St. George's hospitals, excluding all instances in which the condition was due to chronic pulmonary tuberculosis. During the last twenty-nine years 29,700 patients have been admitted to the Brompton Hospital, 567, or 1.9 per cent., with the diagnosis of bronchiectasis. Of these, 59 per cent. were males, 41 per cent. females. Among the 112 cases examined after death, 80 per cent. were males. Among 108 cases in this series the bronchiectasis was bilateral in 47, unilateral in 61. In 18 cases all five lobes of the two lungs were bronchiectatic. Amyloid disease was recorded in six of 108 post mortems. Bronchiectasis is always secondary to some other condition; in this series the primary conditions were: chronic bronchitis 41, pleurisy with pneumonia 27, bronchial obstruction from various causes, new growth, foreign body, aortic aneurysm and syphilitic stenosis 37 cases. The most interesting complication of the bronchiectasis noted in this series was intracranial abscess in 15 of the 108 fatal cases. The common com-

plications of bronchiectasis are inhalation or aspiration bronchopneumonia, empyema, gangrene, and abscess of the lung. The course and duration of the bronchiectasis were very variable, depending upon the severity of the bacterial infection present in the dilated tubes. The principal causes of death in 110 cases were: bronchopneumonia in 34, exhaustion in 34, exhaustion and asphyxia in 8, intracranial abscess in 15, hemoptysis in 5, and a number of other causes in the remaining cases of the series. In all cases inversion of the patient, or letting him cough with his head and chest hanging downward so as to facilitate the emptying of his bronchiectatic cavities, was a serviceable practice, best carried out on waking. Medical treatment aims to combat the infection in the bronchial tubes by antiseptics, the most widely used of which is creosote. Surgical treatment is applicable only to unilateral cases, preferably those in which the lower lobe of the lung is involved.

4. Cycloplegia in Routine Refraction Work.—N. Bishop Harman recommends the use of atropine in the form of an ointment where the routine examination of a large number of children must be made, as in the outpatient department of a hospital or a school clinic. At the Belgrave Hospital printed directions for the use of the ointment are given to the parent by the surgeon in charge. They read as follows: "Put a small piece of the ointment (the size of a match head) inside the lower lid of each eye three times every day, after breakfast, dinner, and tea, until you come next time. Use a wax match with the head cut off for the ointment. The child may not be able to read, but may go to school. The ointment will be stopped when the doctor examines the eyes and orders the glasses. Do not forget to use the ointment, or your visit will be wasted. Be careful with it, for it is very costly. Do not let any one else use it." This routine practice is unsatisfactory for children with blepharitis or eyes scarred from relapsing phlyctenular ulcers.

Journal de Médecine et de Chirurgie Pratiques.

March 10, 1920, xci, 5.

Hemorrhage and Stricture of the Urethra.—Pasteau states that hemorrhagic strictures are more apt to be due to the treatment than to the disease per se. There are, however, exceptional cases of spontaneous hemorrhage which appear to be an essential part of the disease—not including bleeders. These the author terms cases of hematuric stricture. The condition is rare. On the other hand, it is possible to cure stricture without provoking hemorrhage at all. In the rare spontaneous case the blood will usually stain only the last drops of urine voided, but instead it may be the first drops to emerge from the meatus which are blood-tinged. In bleeding at the end of micturition the blood implies the existence of cystitis secondary to stricture. In the opposed case the stream of urine impinges on some point in the urethra which is disposed to bleed.

The Enterorenal Syndrome.—Achard refers to the coexistence of some enteric affection with a secondary nephritis, so that two kinds of symptoms unite to give rise to a characteristic composite disease picture. Several types have been isolated, of which the first is a colibacillary affection of the intestine which is responsible for the development of suppurative nephritis. Heitz-Boyer has notes of 50 such cases, and these present subtypes as the renal, vesical, and septic. In certain cases we see only a colibacilluria without lesions of the kidneys or bladder. In a third major type we do not see suppurative but chronic sclerotic nephritis. Pyelitis of colibacillary origin does not seem to be included in the enterorenal syndrome of Heitz-Boyer.

Le Bulletin Médical de Quebec.

March, 1920, xxi, 7.

Encephalitis Lethargica.—Dr. Sirois reports a case of this malady treated by him at St. Ferdinand d'Halifax last January. During October, 1918, over sixty cases, with 38 per cent. mortality, were treated in the Winnipeg General Hospital. No other Canadian cases are mentioned by the writer. The patient was an unusually well developed and robust boy of 18 years developed chills and fever, headache and prostration. October. He was laid up about three days and recovered promptly and thoroughly. He was occupied with farming until the season closed and then went into mining. Here he worked alternate weekly day and night shifts and overstrained himself, besides getting his stomach upset as a result of unsatisfactory commissary. On January 22 he began to feel ill and developed chills and fever, headache and proctration. He was at once ordered home by a medical man and was treated by his parents with purgation and sweating with the amateur diagnosis of an attack of grippe. On the third day, confined to bed, he complained of a heavy weight on the eyelids and had slept for several days before the author saw him. He seemed in the midst of a normal sleep and replied to questions without any attempt to rouse himself. The speech was low and scanning, but distinct. The temperature was 103° and pulse full and strong at 96. The pillow was drenched with saliva. Headache was still present, but without any suggestion of meningeal involvement, and while the eyes were reddened there was no evidence of ocular pareses save ptosis, which was complete. From the beginning, transpiration had alternated with gooseskin. He ate everything offered him with apparent relish. For two days he remained in the same condition, but became delirious and comatose afterward, dying on the eight day of the disease.

Il Policlinico.

February 1, 1920, xxvii, 2.

Etiology and Pathogenesis of Influenza.—Professor Micheli goes thoroughly and scientifically into the possible etiological rôle of Pfeiffer's bacillus and on no less than seven counts positively excludes it as the cause of the pendemic of 1918. The intense diffusibility and contagion of the pandemic and the impotence of prophylaxis are incompatible with the doctrine that a bacillus like Pfeiffer's could be responsible, for this we have always with us. Bubonic lung plague is due to such a bacillus and we can contend against it fairly well. Pfeiffer's bacillus was assuredly absent from the secretions of the nose and throat in the early days of the infection, despite the fact that it is a domesticated germ liable to be found at almost any time and place. It often appeared in the course of the infection and may have then been a secondary factor, but this is rather evidence against than for it, as the first cause of the malady. The same is true of the common occurrence of the germ in the postpandemic waves which recur in the winters. The germ may be present in the nasopharynx, etc., in healthy subjects when no influence of any type exists. In the pandemic it has never under any circumstances been recovered from the blood. It cannot be made to give the disease to animals or mankind. In like manner every other accused organism can be acquitted of being the first cause of the pandemic, although several are clearly responsible for the severity and fatality of the same. But streptococci and pneumococci cannot have been the first causes of the pandemic any more than Pfeiffer's bacillus. In mild and medium cases these organisms have not been cultivated from the blood. What, then, is the protovirus of the disease? For if we know this we can automatically rule out all other alleged causes. The existence of a very volatile and filtrable virus, should one be proved to exist, will not entirely solve the problem. For example, it cannot explain why one wave may be so mild as to have no mortality when another—perhaps also a first wave—may be so deadly. To account for the latter a true symbiosis may be necessary.

Meningeal Hemorrhage in Lethargic Encephalitis.—Despite the apparent immunity of the meninges in this affection, exceptions have been recorded. Thus Rathery and Bonnard have described a case complicated with hemorrhagic meningitis. After an ordinary début with fever and somnolence the patient developed a meningeal syndrome—positive Kernig and rigidity of the neck. The syndrome persisted a fortnight. The cerebrospinal fluid was frankly hemorrhagic and under high pressure. —*La Presse Médicale.*

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 2, 1920.

THE PRESIDENT, DR. CHARLES H. CHETWOOD, IN THE CHAIR.

EXECUTIVE SESSION.

Resolutions Favoring Universal Military Training.—Dr. GEORGE E. BREWER introduced resolutions to the effect that the Medical Society of the County of New York heartily approved of the plan for universal military service formulated by the Military Camps Association and embodied in Bill No. 3792 now before Congress, inasmuch as this plan not only provided man power for national protection in the event of war, but because, in virtue of its value from the standpoint of intensive physical training and moral discipline of our young men, it would be one of the greatest measures for public health ever enacted by State or Federal authorities.

Dr. BREWER, Dr. CHARLES H. PECK, Dr. GEORGE DRAPER and Dr. FREDERICK T. VAN BEUREN spoke of the advantages of universal military training from the standpoint of physical fitness, the development of moral responsibility, and the fostering of patriotism. It was pointed out that under the plan proposed no great hardship would be imposed on any one, as a young man would be required to spend only three months in training the first year and then from two to three weeks each year for four years. There was some slight opposition to the adoption of the resolution on the ground that the measure was a political one and one with which a medical organization was not concerned. This objection was overruled and the resolutions adopted.

Dr. JOHN P. DAVIN introduced resolutions endorsing the action of the Otsego County Medical Society at its annual meeting in December, 1919, in its condemnation of the Antinarcotic Drug Law and urging efforts to bring about the repeal of this law. These resolutions were referred to the Comitia Minora.

SCIENTIFIC SESSION.

Some Remarks on Group Study in the Surgery of the Head.—Dr. SEYMOUR OPPENHEIMER read this paper, in which he said that the great scope of modern medicine precluded maximum efficiency on the part of one person in all branches. Group study and practice presented the means for providing the needed efficiency for universal enjoyment. In head and neck surgery the ophthalmologist, otolaryngologist, cranial surgeon, neurologist, pathologist, and bacteriologist covered fields the work of which must be combined for completely satisfactory results. The ophthalmologist dealt, for example, with so closely circumscribed a field and one which reflected so many possible systemic or focal conditions that the assistance of the consultants was essential in differential diagnosis. Frequently the most careful group study was necessary in differentiating a sinusitis from an intracranial lesion, though either might be made manifest through headache and eye changes alone. So, too, with each of the specialties mentioned, problems arose which could be solved correctly only by summoning the other members in consultation. Especially well demonstrated had been the value of the otologist to the neurologist in localizing a lesion as between the cerebellum and the labyrinth by means of the more recently adopted ear tests. There were undoubtedly conditions in which these extensive studies were not indicated, but many more occurred in which the brief review of the case by the balance of the group would reveal important conditions which would otherwise be overlooked to the detriment of the patient. The dentist was to-day assuming, and should assume, a much more important function than that of extracting or filling teeth, as these very practices had so much bearing on the welfare of the patient. The skilled Roentgenologist was an ever more important member of the group, as his field developed newer and better methods of head work and their interpretation. The laboratory worker with all the methods at his command was increasingly well recognized as a necessity in really complete, satisfactory, exhaustive study. It was then evident that by combining the results of laboratory tests and close clinical observation, and corroborating them under the guidance of the group, we could hope to elucidate a complex and often obscure symptomatology and secure results to which our patients were justly entitled. Nowhere was this revolution in the practice of medicine more needed than in head and neck surgery.

Group Study from the Viewpoint of the Internist.—Dr. ORRIN S. WIGHTMAN said that Dr. Oppenheimer had given a complete and very careful study of the correlation of symptoms and the valuable assistance which might be secured from group study as related to his own particular specialty. Before discussing the viewpoint of the internist, Dr. Wightman defined group study as a careful and intensive study of the same patient by a number of qualified specialists, who, under favorable surroundings, rendered combined expert opinion. The intent of this opinion was to get a correct and scientific picture of the patient's symptoms and to discover such abnormalities as were present. From the viewpoint of the specialist it was assumed that this system was feasible and that, under group practice, the specialist would be favorably located where he would see a large number of cases daily and where he would be part of a working system which kept careful and scientific data relative to the patient. This would naturally involve properly made out blanks and literature for permanent filing. The specialist in time saw so many cases that were similar that it became routine, and unless he struck a case that was abnormal his interest was apt to wane. He thought that they would all agree that monotony dulled the edge of the physician's enthusiasm. A constant repetition of the same thing tended to make the average individual careless, he lost interest, his work assumed the character of dispensary practice, and he began to go down hill. On the other hand, could the members of any group system, after the day's work, assemble in general consultation, taking their cases seriatim, going through them with a fine tooth comb, and having their results properly tabulated and outlined for the direction of the individual case great good might result. The general practitioner of the present day who was abreast of the times had developed his own system of group study, had a man to look after his surgery, his gynecology, his nose and throat work, etc. He referred his cases to these men promptly and as often as was necessary. The general practitioner was the clearing house where cases coming for his advice and medical counsel received careful consideration. He was in the best position to know the peculiarities of his patients, to save them from shock, from unnecessary annoyances of disagreeable facts which under his guidance could be carefully told and the patient prepared accordingly. He was the man in whom his patients believed and his counsel was necessary for things which were not pathological but had a distinct bearing on the patient's health and well being. Many of the abnormalities which a general practitioner found never gave rise to symptoms and the patient was better off in ignorance of them. Occasionally the unexpected was observed, but the proportion of cases in which this happened did not warrant the extra expenditure on the part of the patient. When the subject was reviewed from the standpoint of the patient, it was found from the examination of men who had applied for service in both the army and navy and from the statistics of life insurance companies that the absolutely normal individual was practically unknown. Sometimes valuable information was secured, although minor ailments as interpreted by the specialist occasionally gave cause for unnecessary alarm. It must be remembered that the average sick person got well without medical service, and that many of his smaller ills never proved a source of annoyance. The patient passing from one physician to another often became confused, as to both his ailment and what he was expected to do in the line of treatment. It must be remembered that patients were human beings who came to the physician sick and unable to help themselves; they needed the clear vision of a disinterested person who could average up their physical woes and guide them accordingly. There must be one man in charge, otherwise the multiplicity

of opinions would nullify all the good that was supposed to accrue to the patient. Looking at it commercially, under a group system the fee to the specialist must necessarily be considerably below what he was in the habit of receiving, or else group study lost its economic value. Reduced to the final dimension, to work most successfully it must mean large business with small profits. Inasmuch as people had always resented being treated as a commodity, would they take kindly to any system that treated them as a commodity, no matter how expert that attention might be? Would the physician lose interest when his patient became institutional instead of individual? When his patients were reduced to case numbers instead of names? There was another phase that might be a temptation to many physicians, namely, to feed the clinic instead of curing the patient. It was questionable whether any good man could give his full interest and enthusiasm to a case for a minimum fee. Corporate medicine which was an extension of group medicine had found its way into public life, but up to the present, aside from the few well known names which were kept for advertising purposes, the rank and file of these medical bodies were composed of young men, recent graduates who had no way of getting started and were glad to obtain the experience with a reasonable stipend, and to hold these positions just long enough to build up a practice. This type of practice might well suit insurance companies and people who had to guarantee the health of their employees, but could hardly meet the requirements of the people as a whole. Group medicine was an excellent way to commercialize a dignified profession when it was linked with the advertiser's art. The attitude of the State toward group medicine was entirely economical. The legislatures had welcomed anything that would take care of the sick irrespective of the fundamental facts. "Keep the people well at so much per capita" had been the slogan for a number of years. The intelligent physician did not need the State law to tell him when he had reached the limit of his skill. As a natural evolution physicians in various parts of the country had worked out centers of international reputation where an intensive study and diagnosis might be made, such as the Mayo Clinic and Johns Hopkins, but these centers had endeavored to lead the way in medical thought and were not meant, with their elaborate methods, to meet the physician's daily needs; they were schools of study and experiment, the results of which were gladly given to the profession. Finally, did the people want group medicine? Time alone would solve this. The essayist did not agree with his predecessor that if the physician did not recognize this need the State would. Group medicine, except in closely populated districts, could not meet the need of the people. People would not want to be handled like a commodity; they demanded to be treated as individuals; they wanted somebody with the human touch who could feel with them, sympathize with them, and help them, and they rightly felt that they were insulted when their ailments were handled like machinery. When the patient lost the type of family physician who had brought him into the world, advised and counselled, controlled and censored him, he had lost a friend who could not be replaced by any State law or legislation.

Dr. Robert T. Morris said it seemed to him these two papers might well be placed side by side in parallel columns as setting forth both sides of the question. Dr. Wightman had expressed the ideals embodied in the old time physician, who was guide, confessor, and friend, a combination of qualities one rarely found in the physician of today. The extreme reaction from this picture lay in group diagnosis. We were between these two positions today. The solution of the whole question, he felt, lay in the enlargement of hospital facilities, so that every physician might have the advantage offered by a group of specialists with hospital facilities and at the same time might carry out the ideals of the last speaker.

Dr. Eden V. Delphey said that he quite agreed with the remark of the last speaker that the two papers of the evening should be placed in parallel columns, as they were to a large extent opposed to each other. Moreover, his own remarks would be somewhat in opposition to those of the last speaker. To paraphrase the words of Mr. Henry Watterson, of Kentucky, who said, "There is no bad whiskey; there are only different grades of good whiskey"—of course this was said before the ratification of the eighteenth amendment—there were no poor doctors; there were only different grades of good doctors. For the last thirty years the medical colleges had been turning out graduates who were well qualified and equipped to practice medicine, although some were better qualified and equipped than others. The only poor doctors were the ones who entered the practice of medicine long before that time, and they are now all dead. Some of these graduates took up the study of a specialty, made rapid progress, and became very proficient in their especial lines, whether they did it for the benefit of humanity or for the money there was in it for themselves. The general practitioner was one who in addition to his knowledge of the science and art of internal medicine had a considerable knowledge of all the various specialties, knew his own abilities and limitations, knew when to treat the patients himself and when to send them to a real specialist—not to one who became a specialist over night—and in that way practiced 'group medicine.' He always sent his own patients to the specialist in whom he had the most confidence, and he had never done so without the specialist's being willing to treat the patient for a fee commensurate with the patient's ability to pay, or even for nothing when the patient could not pay even a small fee. By charging the wealthier patients what the services were worth he was able to do this. He felt that under the care of a good general practitioner the patient had all the advantages to be gained from group medicine as well as those to be derived from the supervision of the family physician.

Dr. Morris Stark said that the diagnostic clinic was not of sudden growth; it had had its inception among the physicians of the hospital staff. When a physician wanted the opinion of a specialist he usually called in some one on the staff of the hospital with which he was connected, and thus the hospital staff came to form a clinical group. Group medicine had its limitations and its advantages. In the first place it should be standardized. Not all groups had standards like those of the Mayo Clinic or the Johns Hopkins Clinic. All the eighty groups in Chicago, referred to by one of the speakers, were not up to the same level. In fact, many of these groups were in reality organized sanatoria for the treatment of cases, and that was a disadvantage. Reference was made to the fact that with group medicine special advice would be made available at a cheaper rate than at present; that was a tacit acknowledgment that the up-to-date specialist was charging too much. Another weak point in group medicine was that a member of a group must accept the services of others in the group instead of being a free lance and sending the patient where he thought best. There were cases in which he wanted the opinion not of one specialist but of several, and it was conceivable that one might want the advice not of one group of clinics but of several. He could not agree with the statement that if they would not accept group medicine they would have to accept State medicine. Before that could happen the medical profession would have to be consulted. In any application of group medicine there would have to be some one to take the supervision of the case, and there should be a standardization of group medicine.

Dr. L. W. Zwisohn said the passing of the family physician was a calamity. Even though special advice was needed, there was still a large field for the family physician; he was a man whose services could not be dispensed with.

Dr. Oppenheimer, in closing, said that owing to the short time allotted for reading his paper, he had not read that portion referring to the internist. He had, however, written that the internist might well be regarded as the keystone of any diagnostic group; that was primarily of the greatest importance. Without the internist no group could succeed. He had not attempted to exploit the advantages of the diagnostic clinic from the commercial standpoint, but simply tried to show the tendency of the times from the scientific side. He thought it was remarkable that a city like New York, which should be a medical center, was

lacking in this advanced movement. In his paper he had simply wished to show that there was a certain group of diseases in which it was very essential, starting with the internist as the keystone, to have the co-operation of specialists in certain other lines of work. He needed in head surgery the internist, the laboratory, the dentist, the *x*-ray man and the neurologist.

Group Study in Urological and Gynecological Surgery.—Dr. DOUGAL BISSELL discussed this phase of the subject, first defining his position with respect to the gynecologist's sphere of work, and what he considered his legitimate field of surgery. He said he was not in sympathy with the popularly accepted definition of the term gynecology as a branch of medical science which related only to the diseases of the organs peculiar to women. He thought it should be more comprehensive and include not only the peculiarities of the female constitution as compared to man, but the diseases of the female urogenital system and their directly dependent complications. The genital and urinary organs were so closely related embryologically and morphologically that a comprehensive idea of one could not be acquired without a study of the other. At maturity their functions and diseases were so intimately associated that no treatise on one subject was complete without the inclusion of the other. After pointing out some of the differences in the anatomical relationships of the bladder and urethra between the male and female, stated that there should be two great divisions made of the study of the urogenital system; one being that of the genital and urinary organs of the male, the other the genital and urinary organs of the female. The study of the genital and urinary organs of the female should again be divided into (1) diseases and injuries which are independent of pregnancy, also those dependent upon remote labor, and (2) those which were incident to or depending upon existing pregnancy, also those which were the immediate result of labor. The first they popularly designated as gynecology, the second as obstetrics. These closely allied subjects frequently met and overlapped; a knowledge of one was essential to a knowledge of the other, and it might be said that a thorough knowledge of either could be obtained only by a comprehensive knowledge of pathology and urology. Dr. Bissell then discussed kidney pathology somewhat in detail, bringing out the point that any displacement of the kidney was conducive to improper urethral drainage, that a ptosed kidney was more predisposed to calculus than a normally posed kidney; the prolapsed kidney was also more prone to tuberculosis. Statistics of the Woman's Hospital corroborated the well known fact that in women the right kidney prolapsed more frequently than the left, and as one would expect there was a predominance of disease on the right side. Fibromyoma of the uterus was among the very common diseases of women that were not infrequently associated with symptoms referable to the urinary organs. When they were removed it was to be expected that the symptoms would disappear, but occasionally disappointment was met with and further search might reveal an associated kidney lesion of equal importance. Cases illustrating this point were cited. Attention was called to the dystopic kidney, which by its presence was a menace to normal delivery. When the pelvic kidney was recognized as complicating pregnancy to the extent of endangering mother or child, cesarean section was usually resorted to. In the writer's opinion surgical effort to readjust the pelvic kidney and free the birth canal of obstruction was as justifiable as to remove a fibroid or an ovarian tumor with the same purpose in view. Dr. Bissell said he had entered somewhat in detail in discussing these conditions to show that the obstetrician and gynecologist needed the help of the urologist, and as for himself, he frequently called the urologist into consultation.

Group Study in Urological and Gynecological Surgery; the Urological Aspect.—Dr. H. G. BUGBEE presented this contribution to the discussion, in which he stated that the pathology, symptomatology, and diagnostic technique which laid the foundation for accurate surgery had, through necessity, become divided among those specially trained and equipped for this work, and this had led to what might be termed the group study of cases. The intimate knowledge which was recognized in consulting those specially informed and equipped (when such special accomplishment was backed by a general surgical experience) should lead to a further division of surgery; and a following through of the case to the end must be most advantageous to the patient. The first-hand knowledge gained by the intimate study of the cases lead to the same attention to details before, during, and after operation, which, in turn, meant better results. These remarks, the writer stated, were especially applicable in the field of urology, and while more particularly applicable to urological surgery in the male, they might often be applied to the female. The association between urology and gynecology was most intimate, and could best be illustrated by the growth of the urological department of the Woman's Hospital. This growth had been due to the recognition of the value and necessity of special investigation of cases presenting urinary symptoms or physical signs pointing to the urinary organs. The writer referred to a paper he had presented before the Urological Section of the American Medical Association in 1915 in which he presented a report on 1,000 urological cases in women in which frequent urination was the predominant symptom, and the cause of this symptom traced in each case. Renal foci with descending infection, or urethral foci with ascending infection, were the conditions present in the vast majority of cases. Subsequent observations in several thousand cases had verified these findings, with the constant increase on the side of renal infection as the primary urinary focus. Trigonitis and urethritis was the picture most often presented. Local treatment often gave relief, but it was often found that measures directed to cutting off the infection at its source must be instituted; this meant, first, the treatment of the patient, and, secondly, the treatment of the urinary tract. To further carry out the team work in the observation and treatment of these cases, a gastroenterological department had been established at the Woman's Hospital. It was surprising the number of cases of urinary tuberculosis that had been discovered after the patients had undergone long periods of local treatment elsewhere; calculi in the kidney or ureter unrecognized and treated symptomatically, the patients often being sent to the hospital for a concomitant or supposed gynecological lesion. The writer pointed out the close relationship between renal infections and gastrointestinal pathology and focal infections and called attention to the possibility of renal anomalies which must always be borne in mind in eliminating an abdominal or pelvic tumor. The discovery of these anomalies had been due to team work at the hospital. Polycystic kidneys, which were of frequent occurrence, were often found in the course of a complete urological examination when not even suspected previously. The writer mentioned a few of the many coexisting urological and gynecological lesions and showed that in order to clarify these cases the cooperation of gynecologist and urologist was necessary in order to pave the way for a relief of symptoms and cure of the lesions. The services of the urologist in this class of patients was not only necessary from the standpoint of diagnosis, but from that of treatment as well. The treatment of bladder growth, lithopaxy, intraureteral manipulations in cases of ureteral calculi, and pelvic lavage in renal infections were especially important. The urologist who, step by step, had marked out the details in the study of the urological phase of the condition was often in a position to operate more intelligently, should surgery be required, and to follow up a case more carefully than a second surgeon to whom data might be given, yet the important aspect of group study lay in cooperation to the benefit of the patient. In closing, Dr. Bugbee emphasized that we must not lose sight of the fact that we were dealing with a human being, not with material to be handed about from man to man, to be manipulated *ad infinitum*. A good history and physical examination were of as much value to-day as ever, and special examinations should be carried out by those whose experience was such that the general clinical picture could be borne in mind. The resultant cooperation would be the treatment of the patient, not a lesion.

Dr. CHETWOOD said that long ago the doctor was supposed to know everything, and consequently was

expected to treat everything from a gunshot wound to measles. Then came specialism, which developed a kind of specialist who saw every ailment from the limited range of vision of his specialty. To-day there was a broadening, and the specialist, in order to make a scientific diagnosis, must have a broad vision. They needed not only group study, but collective study of those departments that touched each other as, for instance, the kidney and the field of the urologist.

AMERICAN MEDICAL ASSOCIATION.

Seventy-first Annual Session, Held in New Orleans, April 26-30, 1920.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 939.*)

SECTION ON SURGERY.

Third Day—Friday, April 30.

Importance of "Vital Capacity" in Thoracic Surgery. (Lantern Demonstration.)—Dr. EVARTS A. GRAHAM of St. Louis, Mo., made this presentation, defining the term, discussing the method of its determination, considering its relation to tidal air, and giving observations on vital capacity in various conditions. Vital capacity represented the maximum respiratory compensation possible in conditions likely to induce asphysia. The average in a normal man of average height had been found to be forty-eight hundred cubic centimeters; it might reach as high as seven thousand and over. A knowledge of the vital capacity made it possible to determine approximately the maximum opening in the chest wall which was compatible with life. In other words, the determination of the vital capacity in a given case would show the individual's ability to compensate for interference with the breathing surface. Mutilating thoracoplastic operations greatly reduced vital capacity, apparently permanently, and such operations, therefore, should be performed only as a last resort.

Prevention and Treatment of Pleurisy.—Dr. JOHN L. YATES of Milwaukee, Wis., reviewed briefly the landmarks in the history of the treatment of empyema. Hippocrates had introduced open drainage in this condition, but until the time of Bowditch little progress had been made. Bowditch had attempted to prevent and to cure empyema by aspiration without producing an open pyothorax. The ideal treatment of empyema involved the cure of serofibrinous pleurisy, and this was best accomplished by means of air-tight one-way drainage, instituted early. This called for early diagnosis. Early diagnosis, the prompt institution of air-tight one-way drainage, and the control of technical details simplified by the use of the fluoroscope to eliminate danger and to minimize failure, were the main points emphasized. The mortality rate and serious complications were much smaller when this method was employed than when open drainage was instituted.

Observations on the Relative Value of the Various Operative Procedures Employed in Acute Empyema.—Dr. CARL EGGERS of New York prefaced his consideration of the subject with the statement that while much had been written regarding acute empyema, nothing had appeared that had radically modified the conception of the pathogenesis or the best routine treatment of the disease. One was impressed by the fact that in most of the papers comparisons were made on the basis of treatment and mortality only. The incidence of the disease, the type of organism, and climatic conditions should be given consideration, as well as the sporadic and epidemic occurrence, and the difference in the disease in different cases. The ordinary conception of empyema was that it was an accumulation of pus in the pleural cavity, more or less encapsulated, following pneumonia. If that had been the only type encountered in the army there would have been little discussion, but it was found following measles, and when the high mortality rate was published, various men tried various methods for the reduction of this high mortality rate. One group of operators considered only the type of infection and thought its removal of primary importance; another group delayed operations until the pneumonia had subsided and then operated. It was necessary to consider what had gone before in order to determine which was the best method of dealing with the given case. If, in addition to studying the clinical features, one would investigate the pathological findings, valuable information would be gained. Pneumococcus infections and streptococcus and staphylococcus infections gave different findings. The methods of operation in use were (1) aspiration; (2) open methods; (3) closed methods. Aspiration did not mean that this should be employed until the case was cured, but only until it was felt that the pneumonia had subsided, when operation should be performed. The open methods, by intercostal drainage and drainage by rib resection, gave good drainage, were easy to perform, and required simple after treatment. In the majority of cases simple drainage, or this supplemented by the Dakin treatment, would bring about good results. The closed methods called for intermittent and continuous closed drainage. Although these methods had been used for years they had never been adopted as universal procedures because they gave inadequate drainage and required cumbersome apparatus. Some of the closed methods of drainage were associated with the injection of formalin-glycerin solution, which was supposed to sterilize the cavity. In some cases it accomplished this, but produced an enormously thickened pleura, and a cast of the cavity was formed by the formalin. No treatment would always give uniform results. Individualization was the keynote of the successful treatment of empyema. The essayist advocated the open method of treatment as a routine procedure. Empyema should be treated by the oldest rule in surgery—when pus is present, give it free exit.

Dr. ALEXANDER LAMBERT, in opening the discussion on the papers of Dr. Graham, Dr. Yates, and Dr. Eggers, emphasized the point that the physician, on seeing empyema in a medical ward, should report the case to the visiting surgeon and not to the house staff. Empyema, as a rule, was not a sequela of pneumonia, it was a complication of pneumonia, appearing generally in the fourth or fifth day. This had been stated years ago by Delafield, and still held true. Pneumonia itself caused more deaths in the early stages of empyema because it prevented the possibility of interference with good surgery. The standpoint of the surgeon, that the pneumonia must subside before operation, seemed to be correct. Whether the pus was "laudable or damnable" made no difference. In many cases there was as much danger from minute abscesses of the lungs as from the empyema. He had had many cases with multiple abscesses scattered all over the surfaces of both lungs. The practice of inserting a trocar into the pleura in pneumonia was to be deprecated. The medical man should be taught to consult the surgeon in the early stages of pneumonia, and that empyema should be treated surgically as early as possible.

Dr. MARTIN B. TINKER of Ithaca, N. Y., said it had been abundantly demonstrated to men in the service that early operation in empyema and pleural effusions caused a large number of deaths. Aspiration and canula treatment was not always successful; it would cure a considerable number, but in many others it was necessary to resect a rib and drain. He emphasized the importance, in using the Carrel-Dakin method, of following the procedure as employed in the War Demonstration Hospital, and not as it was carried out by many others. By the former technique the percentage of cures was very high. If cure did not follow, if relapse and reaccumulation of fluid occurred, rib resection must be resorted to, the resection of one rib and the thorough sterilization of the cavity usually leading to recovery without further operation. Extensive thoracoplastic operations were unnecessary in most cases.

Dr. ARVINE E. MOZINGO of Indianapolis, Ind., described the method which he had employed with success at Walter Reed General Hospital, which consisted in the introduction of a small rubber tube by means of a straight trocar cannula and the removal of the fluid. The tube was fitted into the chest wall and the fluid was withdrawn from one to six times daily. Formalin-

glycerin solution was injected after the withdrawal of the fluid. In a series of 138 cases, 45 of which were acute and the rest chronic, treated by this method there were only two deaths. The amount and the appearance of the secretion and the general condition of the cavity and of the patient were indicative of the time for the removal of the tube. The formalin-glycerine solution should not be used in too large quantity or too long. He had never seen a case of empyema too serious to be treated by the closed method. While delay was advisable in the open operation, it was not necessary in the closed method. There was nothing cumbersome about the apparatus which he employed—it consisted of a two-inch dressing put on by means of four strips of adhesive, holding a medicine dropper.

Dr. JAMES F. MITCHELL of Washington, D. C., thought there should be no controversy regarding the open and closed methods of dealing with empyema, since each in its place was useful. One should not think of empyema as a single condition and center attention upon this, but should consider it only as a part of a more general condition. The treatment could then be selected according to the stage of the disease. Statistics taught very little, but the study of autopsies had brought out some very important points, chief of which was that the empyema attack could be divided into two periods, first, up to three weeks, and second, after three weeks. Autopsy up to the first three weeks showed that several conditions might be present, any one of which endangered the life of the patient. After three weeks the empyema was the chief factor. One must select the time for operation and fit the operation to the time. The three important points were to save life, to reduce convalescence, and to minimize disability.

Dr. MOSES BEHREND of Philadelphia considered the bacteriological control of empyema most important. Treatment could be determined by the bacteriological control. In streptococcus hemolyticus infection no operation should be performed until the symptoms had subsided; in all other cases when pus had formed the sooner it was evacuated the better. Rib resection was the best operation for the purpose. A great deal of harm had been done by other operations, such as thoracotomy and the introduction of drainage tubes. The only way to get rid of pus in any portion of the body was by drainage, and the best way to accomplish this in empyema was by means of rib resection.

Dr. LOCKWOOD of Pasadena, Calif., had had no experience along the line of the experimental researches of Dr. Graham, but he had had considerable practical experience in the front lines. He had seldom caused asphyxia upon opening the chest. It was possible to take up the lungs and to remove fragments of bone or other foreign bodies, and even to remove sections of lobes. He had not done this frequently, but his experience was that asphyxia was slight, especially if the operation was done under local anesthesia. In the treatment of empyema following pneumonia he had had good results from the injection of a two per cent. solution of formalin in glycerin. Judgments as to treatment could not be formed from one epidemic or series of cases. He advocated the routine use of *x*-rays in the treatment of infections of the chest cavity. Bacteriological control in these cases was important.

Dr. CUBBINS of Chicago thought with Dr. Mozingo's method there was danger of making too much negative pressure and thereby injuring the lung. Where aspiration was carried out with lavage the solution would dissolve out the heavy fibrinous clots, but staphylococcus infection in the pleural cavity would not yield to this form of treatment. Streptococcus and pneumococcus infections would. He suggested the angulation of the drainage tube so that the patient would be comfortable while lying in bed.

Dr. GEORGE J. HEUER of Baltimore, Md., said his experience abroad in treating wounds of the thorax was that when the chest was opened widely, sufficiently to exteriorize the lung completely, there was no respiratory upset. He did not question Dr. Graham's experimental work, but wished he would explain more specifically what he meant by too large an opening. He was convinced that, regardless of intrathoracic pressure relationship, if a man had one lung, whether that lung be collapsed or not, respiration would be sufficient for the period of the operation, an hour or an hour and a half. The subject of empyema was a very large one. The whole effort, made possible by the Dakin solution, was to prevent chronic empyema. When chronic empyema had developed, the important point was to sterilize the cavity, leaving it then to take care of itself. In twenty-four cases of chronic empyema, with three exceptions, he had succeeded in sterilizing the cavity. These three were cases of tuberculous empyema, with active pulmonary tuberculosis. In the majority of the cases the *x*-ray showed that the cavity was obliterated. The cavity was obliterated, as shown by *x*-ray study, in from three to eight months. The thickened pleura spontaneously disappeared.

Dr. THOMAS of Philadelphia advocated making the opening for drainage in the eleventh interspace instead of the eighth.

Dr. HEDBLOM of Rochester, Minn., emphasized the point that in empyema, acute or chronic, the treatment should be adapted to the patient, regardless of the particular method favored by the surgeon. In a series of 150 cases of chronic empyema treated at the Mayo Clinic during the past two years 51 were practically cured by using Dakin's solution. Some of these had virtually complete collapse of the lung. There remained a group in which neither rib resection nor Dakin's solution sufficed. These cases had lasted ten, fifteen, and one even thirty years. In such cases it was impossible to hope for complete expansion of the lung. After sterilization decortication of the lung was practised in thirty cases. In twenty-seven cases it was necessary to do a plastic operation. There were four operative deaths in the series. Mutilating radical operation was called for only when conservative measures had failed.

Dr. RICHTER of Chicago thought Dr. Graham had been in error in comparing the fundamental respiratory movement of the dog with that of the human being. The transverse diameter of the chest of the human being was twice that of the anterior-posterior. In the dog it was half. The area was tremendously different. The lateral movement of the medium septum in the human chest was trifling in comparison with the lateral movement of the medican septum of the dog's chest. When one opened the dog's chest on one side one diminished the vital capacity to a slight degree, in the human being, to an important degree. One had been so long taught to adequately drain when one found pus that one was apt to forget that the pleural cavity was but a trifling cavity, holding only a centimeter of fluid. In empyema that trifling space was converted into a large space, and one was tempted to make a large incision and drain. The logical procedure, conditions permitting, was to carry out such method of treatment as would quickly bring together the two layers of pleura.

Dr. ROSALIE SLAUGHTER MORTON of New York City had been interested, on the Salonika front, in the difference in the effect of gas gangrene in pleural and pulmonary wounds as compared with muscular wounds. The difference was attributable to the element of pressure. Chest wounds were more open, hence there was not so much pressure, and these patients recovered more quickly than when gas gangrene involved muscular wounds.

Dr. HARBERLIN of Chicago said when one found an empyema patient in extremis the object was to drain the chest cavity or pleural cavity with a minimum amount of shock or reaction to the patient. Many of these patients should have been operated upon weeks before they reached the surgeon. Local anesthesia and rib resection were advocated, removing the pus without undue manipulation, and covering the chest with a layer of sterile guttapercha instead of rubber, gauze or other foreign substance in the pleural cavity.

Dr. GRAHAM, in closing the discussion, said he did not consider it essential to employ a positive pressure apparatus in intrathoracic operations, for definite physical and physiological reasons. The shape of the chest counted for nothing, but the flexibility of the mediastinum was most important. He considered the pressure results in the dog strictly applicable to the human being.

Dr. YATES, in closing the discussion, quoted the statement that the way to cure chronic empyema was

to prevent it. All empyema started as acute pleurisy and not as empyema. The visceral and parietal pleuræ would adhere so long as no microorganisms got between. The ability to make antibodies for microorganisms and to know how many organisms were left behind were important points. Empyema must be looked upon as a therapeutic failure. The early recognition of pleural exudation and the introduction of intermittent or continuous or the air-tight one-way drainage were necessary preventive measures. He had seen between thirty and fifty cases at La Panne treated largely by the Duval method, and later he had had the opportunity of seeing ninety men treated in the same way except that positive-pressure analgesia was used, as introduced by Gwathmey. Positive-pressure analgesia as developed by Gwathmey plus primary pleural drainage would do more to make thoracotomy a safe and feasible operation than anything that had come out of the war.

Dr. EGGERS, in closing the discussion, reiterated that there was no one way that was always best in the treatment of empyema; the method employed must be adapted to the case. He did not agree that empyema started as pleurisy; he believed it started as empyema. The aspiration of clear fluid showing streptococci indicated empyema from the very start. It was difficult to decide which was the more important factor, aspiration after the pneumonia had subsided, or some form of drainage. The method employed by Dr. Mozingo was useful for some cases but not for all. He would not consider an empyema patient cured until all fluid was out, until the two pleural layers were adherent, and until the patient presented no symptoms.

Fracture of the Femur: A Plea for a Better American Standard.—Dr. KELLOGG SPEED of Chicago sent this communication which, in his absence, was read in abstract by Dr. Dean D. Lewis: "Brief enumeration of the various methods reported in American literature. Lack of uniformity in case histories, examinaton, description of bone lesion and records of results. Remedies: Hospitalization of every case possible, country-wide use of American Surgical Association fracture history sheet in hospitals. Treatment: 1. For neck of femur, fresh cases, abduction of Whitman; old cases, three main types of procedure (a) freshening or introduction of bone peg, (b) head excision and bony union to pelvis, (c) Brackett's head transplantation to trochanter. 2. For shaft of femur, fresh cases, traction and counter traction in suspension systematically applied and watched, applying either Thomas or Hodgen splint or nail extension; old cases, including nonunion or failure of functional result, intramedullary bone transplants or bone plates; compound or open fractures, debridement and extension. For all cases early movement of joints, massage and electricity. Compilation of results, spread of information, standardization of splints and frames and better American average results."

Dr. JOHN B. WALKER of New York City thought it unfortunate that Dr. Speed had been prevented from reading the paper, for if the war had brought forward one thing more prominently than anything else it was the treatment of fractures. He quoted official statistics with reference to mortality, function, length of hospitalization, and disability to show that our results had been disappointing. For example, from an analysis of about two thousand cases that went through the Surgeon General's Office it was anticipated that about sixty per cent. would be returned to duty and that about forty per cent. would be unable to return to duty. Instead of sixty per cent., it was found that only fifteen per cent. were returned to duty. About fifty per cent. of the cases required hospitalization of between two hundred and four hundred days; the other fifty per cent. between four hundred and eight hundred hospital days. It had been estimated from this series of two thousand cases that there would be perhaps ten per cent. without any shortening, another with three-quarters of an inch, and still another with an inch of shortening. When these were checked up it was found that these percentages were practically doubled. As soon as the standard forms were used it was found that much more careful attention was given to measurements of atrophy, of the shortening, and of the limitation of motion. When the standards forms were introduced records were made. The standard forms adopted by the American Medical Association and the American Surgical Association, and previously by the British Medical Association, should be adopted by all hospitals.

The Use of Bone and Fascia Grafts in the Reconstruction of Bones and Joints. (Lantern Demonstration.)—Dr. ADDISON G. BRENIZER of Charlotte, N. C., presented pictures of three cases of defects in the skull in which autogenous transplants from the tibia were used. Defects in the skull showed little spontaneous tendency to become filled with bone, differing in this respect from long bones, which were filled very rapidly. Autogenous transplants from the tibia became smooth and firmly united in the skull within six weeks, and sealed the opening permanently. Where the breech in any one bone was of long standing, the graft must be autogenous or possibly homogenous, if taken from an individual of the same blood group. Heterogenous tissues, dead after sterilization, might be used, but only as temporary internal splints which were finally absorbed. Fourteen cases illustrated this. Fascia was an excellent material for transplantation because it healed without reaction, both in cases where it was at rest and where severe functional demands were made on it. This applied even where aseptic conditions were not favorable. This was illustrated by nine cases.

Mechanical Stability of Fractures Following Operation.—Dr. PAUL B. MAGNUSON of Chicago based this presentation on one hundred consecutive cases of fractures. The fact that there had been so many forms of apparatus suggested and employed for the treatment of fractures showed that the majority were unsatisfactory in the majority of cases. He had taken as a type fracture of the femur, because this was the hardest to hold. If a mechanical apparatus would hold fracture of the femur it would hold almost any fracture in any other part of the body. The development of the subject involved the consideration of (1) the ivory or key bone versus extracortical plates in transverse fractures, and the mechanics of each; (2) the ivory or bone screw versus metal bands or plates, the relative ease of application and the resultant trauma; and (3) the overlay bone graft and combination intramedullary and inlay graft retained by kangaroo tendon. The Lane plate had been used not because it gave a good form of mechanical union or had given satisfactory results, but because it was easy to apply and required very few instruments. Steel had always been a poorly received guest of the tissues; it acted as a foreign body, and when closely applied in the form of screws placed in contact with bone, pressure necrosis took place and the bone fragments were allowed to move. Ivory, beef bone and bone grafts had been used. Autogenous bone graft was preferable of course. In the operative treatment of fractures traumatism could be reduced to a minimum by the application of simple mechanics. A simple mechanical apparatus which would hold against the pull of the muscles was the thing to use. The principle of the key in the key-way applied to the bone graft involved a simple principle of mechanics and furnished the strongest and simplest form of union for transverse fractures. Ivory could be used. It had the advantage over steel that it did not irritate the tissues and did not give rise to callus which it was necessary to remove. For oblique fractures nothing compared with the ivory or bone machine-thread screw.

Dr. SHERMAN of San Francisco, Calif., said bone would atrophy under pressure from one substance just as from another. The ivory peg would cause this just as would the steel screw. Steel screws did not hold more than a few days. His own opinion was that a plaster cast made to fit the individual was more competent than any internal pressure apparatus. Fractures of the shaft of the femur had yielded very good results from the use of the Lane plate, despite the fact that it was metal, was intended to stay, and did not stay. One source of error in the Lane plate was that it was always plated with silver or nickel, which was always infracted, erosion and absorption of bone following much more rapidly than was the case with a single metal.

Dr. RYERSON of Chicago thought Dr. Magnuson's

method of using key very useful in fracture in a single bone. Intramedullary grafts had been supposed to hinder union by interference with the circulation, but that had not been his experience. In old non-united fractures plates could not be used because of the osteoporosis, nor would screws hold. Autogenous grafts should be used in these cases. Bone should never be denuded more than was absolutely necessary. The key or intramedullary graft possessed an advantage in this regard.

Dr. MARTIN of New Orleans, La., made a plea for the Balkan frame, which could be applied so easily that any student could be taught its application, and which gave excellent results. As to mechanical appliances, no law could be laid down. It took a very good mechanic to put up a fracture with a mechanical apparatus. Steel screws had threads too fine and the least movement of the fracture pulled them out.

Dr. THOMAS of Philadelphia emphasized the point that one should not be satisfied with any form of noncperaitve treatment until the *x*-ray had proved it efficient.

Dr. PAUL A. MCINHENNY of New Orleans, La., emphasized the importance of *x*-ray examination. Immediately upon the arrival of a patient in the hospital or as early as possible he applied extension under a general anesthetic. Sufficient extension could be applied to a recent fracture of the femur to absolutely reduce the overlapping, and if good apposition of the fragments was secured its maintenance by extension would not be necessary. An adequately and properly applied plaster cast was all that was necessary, there would then be absolutely no displacement of the fragments, and atrophy would not be sufficient to allow freedom of movement in the cast before union had taken place. A plaster cast properly applied would not give rise to pressure sores. Assistants with no experience should not be allowed to apply traction or plaster casts. More attention should be given to the immediate reduction, under an anesthetic, especially in fracture of the femur, the application of a thin plaster cast, and the immediate *x*-ray examination of the reduced fracture.

Dr. BRENIZER, in closing the discussion, advocated the use of traction in recent fractures and autogenous grafts in cases of long standing. He had had only unfortunate results with metal splints.

Dr. MAGNUSON, in closing reiterated the importance of putting in a graft that would stay if this method were to be used at all. The key graft, with a screw in each end, would hold. It was then not necessary to keep the patient immobilized and there would not be the tremendous disability of the joint that followed mechanical fixation. He did not advocate operating on any fracture whatever. He had been using ivory since 1908, and he had never had to take a piece out, nor had he heard of anyone else who had. Ivory could not be found in the *x*-ray picture. He had had no untoward results from its use.

(*To be concluded.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEBRASKA STATE BOARD OF MEDICAL EXAMINERS.

November, 1919.

(*Continued from page* 898.)

BACTERIOLOGY.

1. Name five culture media.
2. Differentiate a coccus from a bacillus and give example of each.
3. Describe the organism which is the cause of influenza.
4. Describe a tubercle bacillus.
5. How would you examine a specimen of sputum for tubercle bacilli?
6. Name the portals of infection in (a) tuberculosis, (b) gonorrhea, and (c) anthrax.
7. Tell in detail how to examine a suspected urethral discharge for gonococci.
8. Give in detail your method of detecting malarial organism in the blood.
9. Describe the Klebs-Loeffler bacillus and how do you stain for it?
10. Give a general description of the action of agglutinins and give in detail the serum test for typhoid fever, known as the Widal reaction.

MEDICINE.

1. What are the common means of transmission of pathological bacteria? (b) Through what avenues do they enter the body of the human individual?
2. Discuss the history and symptoms of chronic duodenal ulcer.
3. Discuss the treatment of lobar pneumonia.
4. Discuss the causes of chronic constipation.
5. Discuss the treatment of acute gonorrhea in the male, including instructions to patients.
6. Discuss the early symptoms and early physical findings in a case of acute anterior poliomyelitis.
7. Locate the different lesions that may intercept the arc of the patellar reflex, and name the diseases in which the patellar reflex is commonly lost.
8. Compare the temperature and pulse curves in typhoid with those in lobar pneumonia.
9. Discuss the symptoms and physical findings in acute appendicitis.
10. Name all the conditions that may cause pain in the upper right quadrant of the abdomen.

OBSTETRICS.

1. Name the accidents which may occur to the mother and to the child during labor.
2. What are the complications in obstetrics that would justify an abdominal section?
3. How is a retained placenta to be delivered?
4. What are the uses and dangers of pituitrin? When and how would you use it?
5. What are the dangers to the mother during the second stage of labor?
6. Describe your management and treatment of eclampsia.
7. What abnormal conditions in pregnant women are prejudicial to the life of the mother and child?
8. What are the functions of the placenta?
9. What are the indications for the use of forceps in labor? How are they applied and what are the dangers attending their use?
10. Define ectopic pregnancy. Give the symptoms of rupture of an ectopic pregnancy, and how would you treat the condition?

ANSWERS.

BACTERIOLOGY.

1. *Five culture media:* Beef infusion, agar-agar, gelatin, blood serum, and potato.

2. The *coccus* is spherical; the *bacillus* is rod shaped.
Example of coccus: Streptococcus pyogenes.
Example of bacillus: Bacillus tetani.

3. *The bacillus of influenza* is a very small bacillus. about 1 mikron in length by ¼ of a mikron in breadth; it is aerobic and facultative anaerobic, non-motile, does not form spores, has no capsule, stains slightly with the ordinary anilin dyes and stains well with Loeffler's methylene blue, is Gram-negative, is cultivated best on culture media which contain hemoglobin.

4. *The tubercle bacillus* is rod shaped, is from 1½ to 3½ mikrons in length and about 1/3 to ½ a mikron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying, and nonchromogenic; is aerobic; it resists acids; it grows well on blood serum; stains well by Ehrlich's, Ziehl-Nielsen's, or Gabbett's method; it is Gram-positive.

5. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize

by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods while all other bacteria will appear blue.

6. PORTALS OF INFECTION. *In tuberculosis:* The respiratory tract, the digestive tract, through wounds in the skin. *For gonorrhea:* Urethra, bladder, vagina, conjunctiva. *For anthrax:* The skin, the intestines, the lungs.

7. To demonstrate the *gonococcus:* On a cover-glass make a smear with the discharge as thin as possible and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismarck Brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes,* which have been *decolorized by Gram's stain,* and have taken the counterstain.

8. *In examining for malaria:* "Prepare some perfectly clean and very thin cover slips, and remove all traces of grease. Cleanse the skin of the finger-tip or ear with soap and water, and then with alcohol and ether. Make a *small prick* in the skin. Wipe away the first drop of blood, leaving a perfectly dry surface, so that subsequent drops will not run. Squeeze out a tiny drop about the size of a large pin's head. Touch the apex of this drop with the center of a cover glass, and immediately drop it, face downward, on a perfectly clean slide. Make several such preparations, and reject all those in which rouleaux are present. It is absolutely essential that the red corpuscles should lie flat. Examine with a 1/12 immersion lens and rather feeble illumination. Look in the red corpuscles for the presence of small black specks, often rod-like and showing slow movements of translation. These are surrounded by clear areas. One may also see in the center of some of the red cells clear ameboid areas which show no pigment. Rosette forms may also be visible. These forms of the parasite are always present in cases of malaria which have not had quinine. Other varities are only met with in some chronic cases. Of these there are two chief forms: (1) The crescentic, (2) the flagellated. These are easily recognized. The crescentic bodies are highly refractile, rather longer than a red blood corpuscle, and about 2μ in diameter. Particles of pigment may be recognized in the parasite and also in some of the ordinary leucocytes."—(Hutchinson and Rainy.)

9. The *characteristics of the Klebs-Loeffler bacillus (of diphtheria):* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts.

10. *Agglutination.*—"In the blood serum of persons suffering from certain infectious diseases there exist soluble bodies, called agglutinins, which have the property of rendering nonmotile and clumping the specific microorganism of the disease, and have little or no influence upon other bacteria. This 'agglutination' takes place even when the blood is greatly diluted. Undiluted normal blood can agglutinate most bacteria, but loses this power when diluted to any considerable degree. These facts are taken advantage of in the diagnosis of several diseases."—(Todd's *Clinical Diagnosis.*)

The Widal reaction: "Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. . . . A positive reaction is obtained when all the bacilli present gather in one or two masses of clumps, and cease their rapid movement inside of twenty minutes."—(From Thayer's *Pathology.*)

MEDICINE.

1. *Common means of transmission of pathological bacteria:* By the air, by water, by food, by fomites, by contact with infected persons, by "carriers," by domestic animals, mosquitos, flies, fleas, bedbugs, ticks, rats.

Avenues by which they enter the body: Skin, especially through abrasions and wounds; respiratory tract; digestive tract; urogenital tract; conjunctiva, and directly into the blood, as by bites of insects.

2. "*Ulcers of the duodenum* are very similar in nature and origin to those of the stomach, to which they may be secondary. They occur most frequently in men thirty to forty years of age, and often without any obvious cause. Oral sepsis is not uncommonly present, as also hyperchlorhydria; in some cases chronic nephritis or arteriosclerosis has existed, and in others the lesion follows some operation. The first part of the duodenum is that usually affected, and the anterior rather than the posterior wall.

"*The symptoms* are tolerably characteristic, even apart from the dangerous complications, hemorrhage, perforation, and stenosis. The patient, who may appear to be fairly well nourished, complains of pain coming on after meals, not immediately, but after an interval of two or three hours, and often relieved by taking more food. Beginning with a sense of fulness and heat in the epigastrium, it develops into acute pain located in the right hypochondrium and shooting through to the back. On examination of the abdomen a tender spot is usually to be detected a little above and to the right of the umbilicus. The patient complains much of acid eructations, but vomiting is not a very frequent symptom; when present, it may relieve the pain. The ejecta may contain a certain proportion of bile. The patient is constipated and loses weight during an attack. Frequently he has intervals of complete freedom from pain, in which he can digest anything and enjoy life. In a considerable percentage of cases, moreover, the condition is absolutely latent and free from symptoms until acute manifestations of perforation or hemorrhage supervene."—(Rose and Carless' *Surgery.*)

3. The *treatment of pneumonia* "depends entirely on the type of case, and the condition of the patient. Routine treatment is the worst of all treatments. Answer the following questions before prescribing: Is the patient full-blooded, and is there a full bounding pulse? Is the pulse feeble, irregular, or intermittent?

"In the first case, in a young and previously healthy adult, if there be cyanosis, or signs of dilatation of the right heart, blood-letting to the extent of a few ounces may perhaps relieve the strain, but more generally treatment should be directed to maintaining the strength from the outset.

"In the latter case we can hope for nothing from a depressing treatment, so stimulants must be resorted to, such as alcohol, ammonium carbonate, egg and brandy mixture, quinine, ether, etc. The giving or withholding of alcohol depends upon its effect upon the pulse; should the pulse rate fall and the tongue become moist it may be continued. In asthenic cases, strychnine hypodermically is necessary from the outset, and normal saline may be given by the rectum or by the skin. Oxygen inhalations are used where there is cyanosis, but it is doubtful whether they have saved many lives. When there is evidence of failure of the heart (weakness of the second pulmonary sound, etc.) digitalis should be resorted to. Many prescribe it from the outset.

"The diet should consist of milk, beef-tea, or broths, white of egg, and so on. The patient should be as little moved as possible, and the bed-pan must be used. As in other fevers, an airy room and good nursing are essential.

"Remember that narcotics are not well borne in respiratory embarrassment as a rule. Chloral should be avoided, but *if pain be excessive* a hypodermic injection of morphine does *more good* than harm, notwithstanding that theoretically morphine is contraindicated. It should not be given later than the first few days of the illness. The pain may also be relieved by poultices, which, however, are of doubtful use if carelessly made, or by application of ice. Cold packs applied to the trunk only, and frequently repeated, are very useful in relieving both pain and fever. Depressant antipyretics are to be avoided.

"The results of *serum treatment* are not unequivocally encouraging, but vaccine treatment would seem to be of better promise. Where possible, an autogenous vaccine should be used."—(Wheeler and Jack's *Handbook of Medicine.*)

4. *Constipation* "may be caused: (a) *By the character of the food taken,* being more common in those taking an exclusive meat diet than in vegetarians. (b) *Disturbances of innervation,* more frequently than from any other cause. It is seen in hysterical neurasthenia, brain injuries, simple neglect or lack of proper habit, injuries and disease processes affecting the peritoneum, lead poisoning, nervous dyspepsia, hyperchlorhydria, etc., etc. (c) *Mechanical causes,* among which are weak abdominal musculature, strictures, growths, and the recumbent posture. (d) *Reflex causes* and direct irritation as in fissure of the anus, hemorrhoids, rectal ulcer, prostatitis, and displacement of the uterus or ovaries. (e) *Fever* and other conditions associated with profound toxemia, diminished secretion or excessive abstraction of fluids. (f) *Chronic disease of the stomach, colon or small intestine.*"—(Greene's *Medical Diagnosis.*)

5. "The *treatment of acute gonorrhea* is greatly facilitated by keeping the patient as quiet as possible, and in severe cases by rest in bed. The bowels should move regularly and large quantities of water be taken. The diet should be plain and unstimulating; alcohol, coffee, tea, and condiments being especially interdicted. The patient should wear a suspensory, and some form of gonorrhea bag to catch the discharge; a piece of cotton held in place by pulling down the foreskin over it, is useful for the latter purpose. Sexual excitement of all forms must be prohibited, and the penis cleansed twice a day by soaking in warm salt solution. A hot hip bath once or twice a day is beneficial. The patient should be warned of the contagiousness of the discharge, and particularly of the danger of gonorrheal ophthalmia; the hands should be kept clean, and all towels used by the patient kept apart from those used by others. The so-called *abortive treatment,* in which strong antiseptic solutions are injected into the urethra, is dangerous. *Internal treatment* usually consists in the administration of urinary antiseptics, *e.g.* hexamethylenamine (grains 5 t.i.d.), salol in the same dose, or methylene blue (grains 2 t.i.d.); alkalies, particularly when ardor urinæ is marked, *e.g.* carbonate of soda, or potassium citrate or acetate; and balsamics, *e.g.* oleoresin of copaiba, oleoresin of cubebs, and oil of sandalwood, each of which may be given in from 5 to 10 minim doses t.i.d. in capsules. Bromide of potassium, 20 to 40 grains, on retiring, is the most effective remedy for chordee; the painful erection itself may be relieved with ice water. Injections may be antiseptic or astringent; the former may be used from the beginning, the latter in the declining stages. Any injection which causes much pain is too strong and must be diluted or discarded. The syringe should be blunt pointed and hold about three or four drams. The injection should be given after each urination, and the fluid held in the urethra for three minutes by compressing the meatus. Of the antiseptic injections may be mentioned argyrol, 1 to 5 per cent., protargol, ¼ to 1 per cent., and potassium permanganate from 1 to 10,000 to 1 to 1000. The following are astringent injections; zinc sulphate, grains 10, bismuth subnitrate, powdered acacia, each 1 dram, and water 3 ounces."—(From Stewart's *Manual of Surgery.*)

6. *Early symptoms and physical findings in acute anterior poliomyelitis:* "The onset is marked by moderate fever (101°-103° F.), restlessness, headache, pain in the back and limbs, and muscular soreness. Less frequently there is vomiting or diarrhea, and occasionally convulsions occur. The mind is usually clear. In the course of a day or two a flaccid paralysis makes its appearance, all four extremities and the trunk, the lower extremities, one limb, or, perhaps, only a group of muscles being involved. The legs are especially prone to suffer. The paralysis reaches its maximum in a few hours or days, and then begins to improve, in many cases only a small amount remaining at the end of a few weeks or months. Complete recovery is sometimes observed. The constitutional symptoms soon pass off; sensation remains intact; the sphincters are not disturbed, and there is no tendency to bedsores. The muscles showing decided paralysis lose their tendon reflexes, rapidly waste, and soon yield the reaction of degeneration."—(Stevens' *Practice of Medicine.*)

The virus is found in the brain, cord, tonsils, nasopharynx, lymphatic and salivary glands, and elsewhere. The nasopharynx is probably the site of entry and of egress of the disease.

7. *The patellar reflex* consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire refler arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

A lesion, intercepting the arc of the patellar reflex, may occur in any part of the arc, as above indicated.

Diseases in which the patellar reflex is commonly lost: Locomotor ataxia, poliomyelitis, neuritis, diabetes, general paresis, progressive muscular atrophy, spinal meningitis, cerebrospinal meningitis, Landry's paralysis, syringomyelia, and other diseases.

8. *In typhoid fever:* "In the typical case the *temperature* rises gradually during the first week, reaching 104° to 105°, with morning remissions of 1 to 1½°. During the second week it remains high, with slight remissions; so also during the third week, except that the remittent character is more marked. During the fourth week, or at the end of the third week, the morning record approaches or becomes normal, while the evening temperatures, which are from 1° to 4° higher than those of the morning, persist, but with gradually decreasing height, until by the end of the fourth week the record is 98.6°. The *pulse* is rapid, but the pulse rate is often lower than would be expected in comparison with the temperature (*e.g.*, pulse rate 90, temperature 104°). It is often dicrotic, even in the early stage of the disease. As the disease progresses it becomes weak and rapid, or in grave cases, running and thready.

In lobar pneumonia: "In a typical case the onset is abrupt, with a severe and often prolonged chill, followed by a rapid rise of temperature to 104° or 105°. The pulse is rapid (100 to 120), full, and bounding, and the normal pulse-respiration ratio of 1 to 4 becomes 1 to 3, 1 to 2, or even 1 to 1. . . . The fever having risen to its maximum, usually within the first twenty-four hours, continues high, with remissions, until the fifth to the tenth day, when in typical cases

it falls in a few hours (5 to 12) by crisis to normal or below, with a corresponding drop in the pulse."—(From Butler's *Diagnostics of Internal Medicine.*)

9. *Acute appendicitis* is generally of sudden onset; pain is severe and is located in the right iliac fossa, and is frequently referred to McBurney's point; it is colicky in character, may radiate to lumbar region or to bladder, and is made worse by movement of the right thigh; tenderness and muscular rigidity are present in the region of the appendix; nausea and vomiting may be present; moderate fever (101° to 103°), rapid pulse, and a polynuclear leucocytosis of about 12,000 to 25,000 are usually observed; constipation is common. Many other conditions may simulate the disease.

10. *Conditions that may cause pain in the right upper quadrant of the abdomen:* Cancer, cirrhosis, abscess, or inflammation of the liver; cholelithiasis. cholecystitis; subphrenic abscess; aneurysm of abdominal aorta, or of mesenteric artery; renal colic, pyelitis, movable kidney; ulcer or cancer of duodenum or pylorus.

OBSTETRICS.

1. *Accidents which may occur to the mother during labor:* Lacerations of vulva, perineum, cervix; rupture of the uterus; hematoma of vulva or vagina; inversion of the uterus; formation of fistula between bladder and vagina, or rectum and vagina; rupture of pelvic joints; hemorrhage; syncope; infection; sudden death.

Accidents which may occur to child during labor: Asphyxia; cephalhematoma; fractures; hemorrhages; paralysis; rupture of muscles; infection, including ophthalmia; rupture and prolapse of the cord.

2. *Cesarean section.—"Indications:* The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the *'positive'* indication for cesarean section; there is nothing else to be done. Flat pelves having a conjugata vera of 2¼ inches or less, and justo-minor pelves with a conjugata vera of 2½ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible; but cesarean section is agreed upon to *save the life of the child;* (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a *living* child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by *post-mortem* cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements, may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication."—(King's *Obstetrics.*)

In addition, abdominal section may be required for abdominal tumors, for suppurative peritonitis, for ectopic pregnancy, and in puerperal sepsis.

3. In *retained placenta,* "all that is necessary to secure its delivery is the proper application of the Credé method. Occasionally it is held in place by atmospheric pressure, and the Credé method fails to dislodge it. In such cases the finger may be hooked over the edge of the placenta, and the air let in behind it, when its expulsion will be easily secured. A retained placenta is not attended with bleeding, while an adherent placenta usually bleeds profusely. It should be a rule not to repeat the dose of ergot until the placenta is delivered. If the placenta is adherent. as is usually shown by the bleeding, the large size of the uterus and the complete failure of the Credé method, it must he extracted manually. Unless the bleeding justifies it, manual extraction should not be considered until after one hour after delivery. After careful cleansing not only of the hand, protected by a rubber glove, but of the vulva and vagina, the whole hand is inserted in the vagina, following the cord up into the uterus. The fingers are inserted under the edge of the placenta, and it is gradually and gently peeled off the uterine wall. If any adhesions, too dense to be separated in this manner are felt, they may be pinched through with the thumb and forefinger. The loosening of the placenta is materially aided by compression by the free hand upon the fundus, through the abdominal wall. When the placenta is entirely detached no effort is made to extract it, but the uterus is stimulated to contract by kneading it with the free hand on the abdomen, and is made to expel the hand and placenta together."—(Hirst's *Obstetrics.*)

4. *Pituitrin* "is given intramuscularly and not subcutaneously, in doses of one-half to one mil. It is a powerful stimulant to all unstripped muscle, and if used recklessly is a most dangerous drug. Its action on the uterine muscle is of greatest intensity when the patient is already in labor; it is not so intense when used to induce labor; and as an abortifacient it is entirely unreliable. If used according to the following directions, its use should be followed by gratifying success: (1) It should be given in primiparæ only when the head has passed through the cervix. (2) It should be given in multiparæ only when the cervix is thoroughly effaced, fairly dilated and easily dilatable. (3) It should never be given to any patient, if there is any obstacle to an easy delivery. (4) One-half mil. doses are as effective as one mil. and safer. (5) It should be given deeply intramuscularly, preferably in the deltoid, and not subcutaneously, and, above all, *not intravenously.* (6) Overdose is liable to be followed by relaxation of the uterus and postpartum hemorrhage. More than two mils. as a total amount should not be used in any labor. (7) In syphilitic patients, the danger of rupture of the uterus is greatly increased, and pituitrin should not be used at all. (8) Stronger solutions are on the market, for use after surgical operations. This "surgical" pituitrin should be avoided in obstetrical work. (9) If inertia occurs early in the first stage of labor, before the os is well dilated, three doses of three minims each, an hour apart, often act very well. *Accidents from its use* have been: Rupture of the uterus; fetal asphyxia from violent uterine contraction; post-partum hemorrhage; premature separation of the placenta; extensive laceration from precipitate delivery."—(J. C. Hirst's *Manual of Obstetrics.*)

5. *Dangers to the mother during the second stage of labor:* Laceration of perineum or cervix; rupture of uterus; inversion of uterus; hemorrhage.

6. ECLAMPSIA.—*Prophylactic treatment* consists in the proper care and examination of the woman during pregnancy; metabolism must be kept as perfect as possible; the eliminative organs must be working; constant examination of the urine for nitrogen output and presence of albumin) must be made; the diet must be regulated; headache, disturbed vision, nausea, edema must be investigated.

Active treatment consists in reducing the blood pressure; administration of purgatives, diuretics, and diaphoretics; administration of chloral, veratrum, or chloroform; and sometimes it is necessary to empty the uterus.

7. *Abnormal conditions in the pregnant woman which are prejudicial to the life of mother or child:* Misplacements of the uterus; toxemia; nephritis; endocarditis; pernicious anemia; tuberculosis; syphilis; poisoning by lead, tobacco, or mercury; eclampsia; ectopic gestation; asthma; pneumonia; variola; scarlet fever; erysipelas; traumatisms; diseases of the genital tract.

8. The *functions of the placenta* may be summed up as follows: (1) It is nutritive, allowing of the passage of nutritive material to the fetus. (2) It is respiratory. Oxygen passes to, and carbon dioxide from, the fetus. (3) It is excretory, allowing the escape of urea and other products of fetal metabolism. (4) It has a glycogenic function. Glycogen is stored in its cells for the future use of the fetus. (5) It is iron storing, by which iron in organic combination is passed from the maternal circulation into the fetal circulation to be stored in the liver cells of the fetus, in order to aid in the formation of new colored blood corpuscles.—(Lyle's *Physiology.*)

9. *Indications for the use of forceps are:* "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 2. *Passenger at fault:* A. Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute).

Accidental complications: Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother and child, or both."—(From Jewett's *Practice of Obstetrics.*)

Manner of using forceps: "They should not be used when the os is undilated, when the head is not engaged, except in placenta prævia, when the membranes are unruptured, when the disproportion between the child's head and the parturient canal is too great, or in impossible positions and presentations. Before applying the instruments they should be sterilized, preferably by boiling; and the patient anesthetized and placed in the lithotomy position. Two fingers of the right hand are introduced into the vagina; the left blade of the forceps is then held almost perpendicularly by the left hand, with the tip of the blade opposite the vulva; the tip is introduced into the vagina, and passed along the floor toward the sacrum. The blade is rotated outward in its long axis in order to escape the promontory of the sacrum. The right blade is introduced in a similar manner. To facilitate locking, one of the blades must be rotated forward. If the head occupies the right oblique diameter, as in L. O. A. and R. O. P. positions, the right blade must be rotated; if it occupies the left oblique diameter, the left blade must be rotated. Traction is made in the direction of the pelvic axis until the perineum is well distended. The perineum is then protected by one hand, while the face is swept over it by an upward movement of the forceps. In posterior positions it is necessary to remove the instruments after the head is drawn down to the pelvic floor; after anterior rotation is secured they may be reapplied. If the occiput rotates into the hollow of the sacrum the hands should be depressed as the face is swept out under the symphysis pubis."—(*Pocket Cyclopedia.*)

The *dangers in the use of forceps* are: Sepsis, injuries to the soft parts or to the child, and hemorrhage. All antiseptic and aseptic precautions should be observed, extraction should not be made too rapidly, the utmost care must be employed, compression on the fetus (particularly on the skull) must not be too prolonged, the mother's bladder must be emptied, and traction should be exerted only during the pains.

10. *Ectopic pregnancy* is a pregnancy in which the fetus is developed in some place other than the cavity of the uterus. *The symptoms* for the first few weeks are exactly similar to those of normal pregnancy. Later, sharp, cramp-like, periodic pain occurs and is reflected down one thigh. About the third month menstruation returns. The bleeding is profuse and attended by some pain. Flesh-like masses (decidua) are discharged. Nearly all the signs of normal pregnancy are present. Physical examination will reveal a softened cevix, an enlarged and displaced uterus, and the presence of a small cystic tumor, sensitive and adherent, on one side of the uterus. *Rupture* is attended by great pain and syncope. If the hemorrhage is intraperitoneal and extensive death results in a few hours, attended by symptoms of profound shock; rapid, weak pulse; blanched, cold skin; sighing respiration, and fall of temperature. If the hemorrhage is extraperitoneal, it will be limited and the symptoms of shock and bleeding will be slight. Before rupture the diagnosis is difficult, but afterward the history of early pregnancy, intense pain, syncope, and collapse will distinguish this condition. The *treatment after rupture* is—laparotomy. "After thorough cleansing and sterilization of the abdomen and pubes, as well as of the instruments and hands of the operator and assistants, the bladder is emptied and the patient anesthetized. An incision 3 inches long is then made in the median line above the pubes down to the peritoneum, any bleeding vessels being twisted before opening the peritoneal cavity. The peritoneum is then incised; the intestine kept back by pads of cotton or gauze wrung out of sterilized water; the operator's fingers bring out the distended tube and ovary at the incision after having freed them from any existing adhesions; the pedicle is then transfixed by a double ligature of sterilized silk, and each half of it tied securely according to surgical rule. The pedicle is cut, and the entire mass—the Fallopian tube, with the cyst, fetus, ovary, and effused blood, removed, extra care being taken, in the ruptured cases, to quickly secure the bleeding vessels of the ruptured tube from further hemorrhage. The pads are then withdrawn and the abdominal incision closed and dressed in the usual manner. In case of threatened collapse from hemorrhage during the operation, the peritoneal cavity may be flooded with a 1 per cent. sterilized solution of common salt at a temperature of 100° F., a quart of this solution having been previously prepared. It is rapidly absorbed by the peritoneum, and acts as a restorative—like transfusion."—(King's *Obstetrics.*)

ON RETROGRADE STRETCHING IN THE TREATMENT OF IMPERMEABLE CARDIOSPASM.*

BY MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE SCHOOL; VISITING PHYSICIAN TO THE LENOX HILL HOSPITAL.

A FEW years ago I described two cases[1, 2] of impermeable cardiospasm successfully treated by retrograde stretching by means of the pyloric dilator. Inasmuch as these cases are not very common and present rather considerable difficulty in their treatment I thought it of interest to report a few cases and discuss their management.

As regards the term "impermeable cardiospasm", it signifies, as is well known, failure of food to enter the stomach in the normal way, absence of organic stricture, and impossibility of reaching the stomach by the usual gastric tube or a bougie.

FIG. 1.—Roentgenogram of the esophagus of B.R.P. after the injection of bismuth; the esophagus shows diffuse dilatation and the cardiac opening lies away from the center.

Experience teaches that two groups of impermeable cardiospasm may be discerned:

1. The bougie nearing the cardia engages in the sacculated wall of the esophagus, and here meets with a slight resistance. If one tries to push the bougie farther in, one has the sensation as if one pushed the thin elastic wall further down. This may be done gently without much force, when one distinctly feels the esophageal wall being pushed down and coming up again following the olive end of the bougie.

FIG. 2.—Roentgenogram of B.R.P. with the duodenal tube in place. There is some barium in the stomach; the tube end lies in the beginning of the small intestine.

2. The bougie strikes the cardia but fails to enter it. Here again two varieties are encountered: (*a*) The bougie meets with a distinct resistance and cannot be pushed any further (spasm and fixation of cardia); (*b*) The bougie meets with a resistance at the cardia, failing to pass it; it can, however, be pushed further down for two or three inches, moving the closed cardia for that distance into the stomach, without entering the lumen (movable cardia).

An illustration of group 1 is given by the following case which I observed very recently:

CASE I.—November, 1919. B. R. P., 40 years old, had grippe about 10 months ago. Thereupon the patient began to suffer from distress in his epigastrium pretty soon after eating. Patient noticed difficulty in swallowing liquid and solid foods. He felt as if the food collected at the pit of the stomach; and he was unable to force it down without water and without much straining at that. Then after such effort, he would feel the food suddenly drop down into the stomach.

For the last four months vomiting occurred almost every day, large quantities being brought up at once

*Read before the Assoc. of American Physicians at Atlantic City, N. J., on May 5, 1920.

without much effort. Occasionally the patient wakes up at night with constriction in the chest and vomiting. For the last three months he has noticed that he could not partake of ordinary food without the help of water. He experiences difficulty in eating and pains

FIG. 3.—Roentgenogram of B.R.P., showing the pyloric dilator; the inflated balloon is just in front of the cardia in the stomach.

in the scrobiculum. For the last six weeks no food whatever has agreed with the patient, almost everything being vomited during the day or night. He has lost 20 pounds during his sickness, especially during the last four months. He feels extremely feeble and can hardly walk. Examination of the patient fasting—showed that the esophagus contained 300 to 400 c.c. of undigested food, which appeared through the stomach tube lodged in the esophagus and through vomiting. A bougie (No. 43) entered 17 or 18 inches and struck

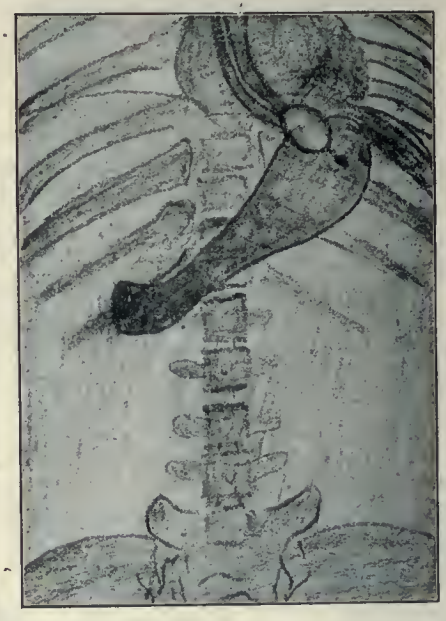

FIG. 4.—The same as Fig. 3; the dilator has been pulled up about two inches or more without passing through the cardia, the latter being simply lifted and invaginated into the esophagus.

the esophageal wall, as evidenced by a feeling of elasticity of the wall upon pushing the bougie gently further in, but did not pass the cardia. Swallowing sound was absent.

Based upon these findings the diagnosis of a dilated esophagus and impermeable cardiospasm was made and patient was referred for further observation to the Lenox Hill Hospital. The duodenal bucket passed the cardia and entered the duodenum in 24 hours. The string showed bile below 24 inches and a blood stain at 17 inches. The test apparently showed the presence

FIG. 5.—The same case as shown in Fig. 4; the balloon of the dilator has passed the cardia and is within the esophagus.

of an ulcer of the stomach near the cardia, which was probably the cause of the cardiospasm.

An *x*-ray picture of the esophagus taken by Dr. Thomas Scholz corroborated the diagnosis of dilatation of the esophagus, due to cardiospasm.

In order to cure the ulcer and to afford relief to the dilated esophagus it appeared best to keep the patient on duodenal alimentation. The tube was introduced in the afternoon of October 20, 1919, and the following day feeding by the tube through the duodenum was commenced. The patient felt much relieved and strengthened within a few days. There was no vomiting and he slept well. After eight days of duodenal feeding the tube was removed. October 28, 1919, the pyloric dilator was introduced. On the following morning the balloon of the instrument was found to be in the duodenum. Stretching of the pylorus and then of the cardia (up to 60 F.) was then easily performed.

During the month of November, 1919, stretching of the cardia was undertaken every other day, a ballooon of 70 F. passing through without much difficulty. Patient could eat quite well and did not vomit. He gained considerably in weight.

Figures 1-5 show the dilated esophagus of the pa-

FIG. 6.—The inflatable dilating bougie.

tient P., with the cardiac opening lying to the side, away from the center, and the different steps of the method of retrograde stretching by the pyloric dilator.

It was soon discovered that after a few stretchings with the pyloric dilator, bougies could now be introduced and reach and pass the cardia.

The usual metal cardiodilator was then introduced for further treatment, and the cardia was stretched twice up to 80 Fr. and ultimately to 110 Fr. The patient could now eat like any ordinary individual without experiencing the slightest inconvenience.

Group II, subdivision a, may be represented by the following case:

CASE II.—March 17, 1919. Mrs. A. R., about 40 years old, has suffered from dfficulty in eating, choking and vomiting for the last twelve years. Frequently she would have to leave the table in the middle of a meal in order to eject the food, on account of a feeling of suffocation she experienced. She never could eat with ease like other people. She was forced to gulp down a quantity of water, in order to make the food go down. I saw the patient first during the spring of 1917.

The findings were as follows: Swallowing sound absent; bougie with olive No. 43 meets resistance, which is impassable, at 16 inches from the lips. This spot of resistance is stationary and cannot be pushed down, or made to move even a little bit. Olive No. 48 shows exactly the same condition.

During March, 1919, a chance for the reexamination of patient presented itself. Again the findings were exactly the same: Swallowing sound absent; bougies with olives Nos. 38, 43, and 54 meet with an absolute impassable resistance at 16 inches distance from the lips. The stomach tube introduced 16 inches into the esophagus in the fasting condition of the patient brings up 150 c.c. of food from the day before with the following characteristics: Reaction acid; No HCl present; rennet absent; lactic acid present.

The patient then entered the Lenox Hill Hospital for observation and treatment. The duodenal bucket entered the duodenum and showed on the string a blood stain from 22½ to 23 inches from the lips; from 24 to the end it was stained a golden yellow.

A diagnosis of severe impermeable cardiospasm complicated by duodenal ulcer was made. The patient was kept on duodenal alimentation for two weeks. This afforded perfect rest to the dilated esophagus, stomach, and the upper part of the duodenum.

After removal of the tube, the pyloric dilator was introduced, and after a night's sojourn, it entered the duodenum. The pylorus, and then the cardia were stretched retrogradely. This procedure was kept up for two weeks, both pylorus and cardia being stretched about twice a week. Thereafter stretching of the cardia alone was employed, first twice weekly, and later once a week. The patient made a rapid recovery, gaining in weight steadily and being able to eat almost all kinds of food like ordinary people.

Group 2, subdivision *b*, is well represented by the following case:

CASE III.—December 10, 1919. Mrs. F. F., 25 years old, married, no children, menses normal. She had scarlet fever as a child—good recovery; operated upon for goiter at the age of 9.

The present history dates back to four years ago, when the patient was suddenly frightened and fainted. After this for about some time she had a fear of people. This lasted about one year and cleared up. This was followed by pain in left iliac fossa, at first, and then by pains all over the body. The patient was unable to eat, and had great difficulty in swallowing. She had a choking sensation in her throat continuously—whether she ate or not. Two years ago vomiting began. The patient would vomit during meals and between meals. The vomitus at times contained undigested food and at other times consisted only of mucus—never any blood.

When the patient would eat, she would feel as though the food was going to choke her. At times the food would go into the stomach and again it would not go beyond the mouth. But the patient would vomit even though no food entered the stomach. The bowels were constipated.

For the past four months two to three days would elapse during which the patient could not eat; even water was swallowed with difficulty. The bowels were constipated during the past 3 or 4 months for a week at a time, unless she took an enema. The pain was very severe in the epigastrium for the past few months. The patient slept well during the entire period of her illness. She last 36 pounds in the past 4 years, most of which was lost in the past six months, though just how much the patient does not know.

The physical findings were as follows: Swallowing sound absent. Bougies 38 and 43 meet with a resistance at 16½ inches from the teeth. Upon pushing the bougie further down, the resistance (cardia) can be moved for fully 2½ to 3 inches downward, the bougie failing to pass through the cardia. A stomach tube, introduced 15 inches from the teeth, into the esophagus of the fasting patient brings forth about 120 c.c. of food residue, showing the following: HCl absent, lactic acid present, rennet absent.

The diagnosis of movable cardia and impermeable cardiospasm was made, and the patient was referred to the Lenox Hill Hospital for further examination and treatment.

The duodenal bucket was introduced, atropine being given, and entered the duodenum over night. The string showed bile beyond 24 inches and a blood stain at about 18 inches. The patient was then given the duodenal tube with atropine medication. The next day the tube entered the duodenum. She was then treated by duodenal alimentation for two weeks. She felt well, vomited very little during the entire period of treatment, and picked up in strength.

After the withdrawal of the tube, the pyloric dilator was introduced and with it liquid food by the mouth and atropine were given. The next day the pyloric dilator was found to be still in the esophagus above the cardia. It was left in the digestive tract for another period of 24 hours. When examined 48 hours after its introduction the dilator was found to be in the duodenum. Stretching first of the pylorus and then of the cardia was now easily accomplished. While, however, we could pull through the pylorus a balloon corresponding to No. 65 Fr., the cardia did not at first permit a larger balloon than No. 50 Fr. A few days later, however, we succeeded in pulling through a No. 60 Fr.

After these retrograde stretchings the patient could eat with greater ease and vomited but seldom. Her esophagus was washed out every other night. At first 100 c.c. of food residue would be found; later on the amount was 50, and ultimately 40 c.c.

A new attempt was then made to pass a bougie through the cardia, for it was believed that the spasm was much diminished. This proved correct. At first we succeeded in passing bougie No. 48 through cardia after pushing it down 18½ inches. A few days later bougie No. 54 passed the cardia in the same manner as No. 48 and entered the stomach.

Later on we made use for the retrograde stretching in this particular case of a new instrument which resembles the aspirating bougie, namely, the "inflatable dilating bougie."

The patient has gained 12 pounds in weight since we succeeded in stretching her cardia and eats fairly well.

I herewith give a drawing of this cardiodilator, the construction of which is apparent and needs no description. The advantage of the inflatable dilating bougie is that it can be introduced at once into the stomach, without a period of waiting which is necessary with the pyloric dilator, and the stretching performed immediately after inflating the baloon. (See Figure 6).

I have observed a few more cases belonging to the two groups just described. I shall refrain, however, from recording them as they would be almost a repetition of the cases above detailed.

Altogether I have had ten benign cases of impermeable cardiospasm. Two (about eight or ten years ago) had been operated upon by Dr. Willy Meyer; in one, Mrs. P., an esophagoplication was made with great benefit to the patient for about six months, when later she succumbed to an empyema. The second patient, a Mr. D., was in such extremis when first seen by me, that a gastric fis-

tula was the only feasible procedure to begin with. He died as a result of perforation of the esophagus occurring a few days after the establishment of the fistula.

The other eight had all been treated by retrograde stretching of the cardia, some after a previous course of duodenal alimentation. All of these patients benefited greatly by retrograde stretching. They could eat with greater ease and did not vomit as much. In some of them after a few stretchings the cardia became accessible to direct treatment (*i. e.* the impermeable cardiospasm was converted into a simple permeable cardiospasm).

There are a few points concerning impermeable cardiospasm I would like to broach.

1. As regards the etiology of impermeable cardiospasm, as well as of plain permeable cardiospasm, gastric ulcer, especially if situated near the cardia, seems to play a dominant part. In the new cases here described as well as in a great number of others, observed in my practice, I have found the association of the two conditions present. What is more natural than to assume that the ulcer is the original cause of the persistent spasm? In this connection I would like to mention another point which relates to the connection of peptic ulcer and cardiospasm.

In cardiospasm the swallowing sound at the cardia is always absent. In a number of patients with ulcers near or within the cardia I have found the swallowing sound absent, and this even in cases in which there was apparently no delay in the entrance of food from the esophagus into the stomach. Moreover, I know of two patients who had cardiac ulcers years ago, which have healed perfectly, who have ever since shown an absence of the cardiac swallowing sounds. It seems as if the ulcer near the cardia by its presence, and later by its healing, interfered with the normal function of the cardia. While the food may pass through this opening in due time, still the normally heard sounds are no longer present, probably because of some alteration in the structure of the cardia.

The absence of the swallowing sounds in some cases of ulcer near the cardia again show the intimate connection between gastric ulcer and interference with the normal work of the cardia.

2. The diagnosis of benign impermeable cardiospasm is usually quite easy to establish. In group 1, that of sacculation of the esophagus with the opening lying somewhat away from the center, the bougie strikes the esophageal wall at the bottom. This can be pushed down a little, giving the sensation of a thin elastic pliable membrane. Extreme caution is required in the performance of this test, as forcible pushing of the bougie might penetrate or injure the esophageal wall.

In group 2, subdivision (*a*), there is often the thought of a neoplasm presenting itself. For the bougie meets with an impassable resistance at about 16 inches which at first sight simulates a growth. There are, however, the following features which will help to establish the diagnosis: In benign cardiospasm there is usually a long history of trouble, two to ten years or more. There are besides frequent intermissions during which patient partakes of food pretty easily. In a real neoplasm there is a comparatively short history of a steadily progressing trouble, without any periods of freedom. The duodenal bucket and frequently the pyloric dilator enter the stomach after a night's sojourn in the digestive tract. Usually it is possible to pull from the stomach through the cardia a balloon measuring in size 55 to 60 m.m. in circumference, if not more. In cancer these attempts will remain unsuccessful. The *x*-rays will frequently likewise, help to establish a correct diagnosis, with some exceptions.

3. As regards treatment retrograde stretching with the pyloric dilator appears to be preferable to passing bougies over a previously swallowed string. It sometimes happens that even a flexible instrument can not follow the string, if there is present too great a bend in the sacculation or an unyielding spasm at the cardia.

In cases in which an ulcer in the stomach is suspected or really discovered, it is advisable first to accord the esophagus and stomach a period of rest (by duodenal alimentation) before instituting the stretching treatment. The latter is best done first by the pyloric dilator, every other day or twice a week, the dilator being introduced before retiring supplemented by a dose of atropine, and the stretching done the following morning. After a few stretchings the dilator enters the stomach in a much shorter time. It can then be passed early in the morning, with atropine, and stretching performed one or two hours later, as soon as the balloon has reached the stomach. This can be easily ascertained either by the *x*-rays or by inflating the balloon, and then pulling it upward. In case the balloon is in the stomach a resistance is felt as soon as the instrument reaches the cardia. If no resistance is encountered, the balloon is deflated the patient given some water or tea to drink, and after waiting one-half hour or so, the experiment is repeated. The entrance of the balloon into the stomach must be patiently watched and tested, and when found in the latter retrograde stretching can be undertaken.

Stretching in situ can also be done by the double balloon pyloric dilator. This is more effective but the instrument is somewhat coarse and harder for the patient to manage.

In some of the cases treated after a few retrograde stretchings the cardia becomes accessible to direct instrumentation. In these instances the usual method of stretching can be carried out by the common instruments in use for the dilatation of the cardia.

In some cases of marked cardiospasm with considerable dilatation of the esophagus, besides the stretching, the esophagus was washed out every night or every other night. This gives much relief to the patient and is also of value with regard to gauging the improvement. As soon as there is a real change for the better, the amount of residue in the esophagus becomes less and ultimately disappears.

THE ANESTHESIA PROBLEM IN LUNG SURGERY.*

By JAMES TAYLOE GWATHMEY, M.D.,

NEW YORK.

THIS paper is based upon between eighty and one hundred animal experiments conducted in the Central Medical Department Laboratories, A. E. F., Dijon, France, and a large clinical experience with surgical teams working in the advanced zone of the American Army and confining themselves almost exclusively to chest surgery.

Both the anesthetic agent and the method to be employed were thoroughly tried out, and were finally decided upon sometime before entering upon the surgical duties at the front.

The Agent.—Patients who require thoracic surgery usually have other injuries and are more or less shocked, suffering, among other things, from lowered blood pressure. Inasmuch as one of the clinical features of chloroform anesthesia is lowered blood pressure, and for other reasons, chloroform was not considered. In the writer's opinion it should not be used at all in war surgery, except, possibly, in a 50 per cent. solution with ether, and then only as a preliminary to ether, or for very short operations, and never as a terminal anesthetic. The final choice lay between ether and nitrous oxide and oxygen. Both these agents were used in our animal experiments.

Anesthetic of Choice.—Other things being equal, the agent selected should sustain the blood at the highest possible level consistent with good surgical anesthesia during the operation and with a minimum of reaction after operation. In general narcosis with ether or nitrous oxide and oxygen the blood pressure depends more upon the depth of anesthesia than upon the agent, and if the same technique is used it is sustained as well with the one as with the other. Crile,[1] unfortunately, published a misleading chart that seems to show that "an animal under nitrous oxide anesthesia endured shock-producing trauma better than an animal under ether anesthesia," using the irregular and unscientific drop method of ether for the comparison of the two agents. (See chart.) Every surgeon knows that the blood pressure does not fall in this way under ether during operations requiring extensive trauma.

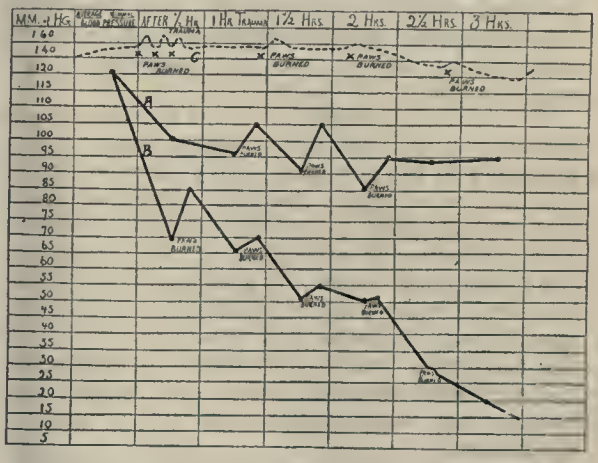
Dr. Carl Connell and the writer[2] paralleled the experiments of Crile, following his technique absolutely, traumatizing the animal and continuing the experiment for the same length of time, but giving the ether by the vapor method pharyngeally, so that the quantity of ether and the volume of air were so regulated that an even anesthesia was maintained at all times.

The chart made from these experiments seemed to prove that animals under ether, properly given, stand shock as well as those under nitrous oxide anesthesia. But neither Crile nor Connell and the writer carried observations beyond the immediate experiment.

Marshall[3] of the British Army verified the work of Connell and myself, and disproved the work of Crile, by showing clinically that the blood pressure is sustained equally well under ether vapor and with nitrous oxide and oxygen, the ether in Marshall's cases being given in probably the safest and best possible way, that is, warmed and oxygenated and by the vapor method. He carried his investigations further, however, and, following his patients through the shock ward, found that in a few hours a lowered blood pressure succeeded the ether administration that did not obtain when nitrous oxide and oxygen were administered.

Cannon[4] states that it was found that ether caused in a shocked animal a fall of blood pressure which might be as great as 30 or 40 mm. of mercury, even though only a sufficient degree of anesthesia was induced to barely abolish simple reflexes. He holds that if the same degree of anesthesia be maintained with nitrous oxide and oxygen, the reflexes could be abolished with no fall of blood pressure whatever. Since Cannon does not use heat and oxygen with the ether, but uses air at room temperature, the comparison, in my opinion, is not a fair one.

Marshall's work and charts, in connection with



Composite tracings (Crile): A, Nitrous oxide (plus oxygen); B, ether (by the open drop method) Connell and Gwathmey; C, ether by the endopharyngeal method.

collateral data, caused us to decide upon using *nitrous oxide and oxygen.*

The Method.—The endotracheal and endopharyngeal methods are used successfully in lung surgery, as far as the immediate operation is concerned. Each method requires an initiatory anesthesia so deep as to abolish all reflexes before the insertion of the tubes. This initiatory anesthetic favors lowered blood pressure and lowered temperature, and would be a serious handicap to a patient previously exsanguinated or in a state of shock from other causes, and might possibly prove fatal. The endotracheal method is an operation in itself, requiring additional time, and accidents occasionally occur. For these reasons both methods were discarded for a safer and simpler one.

Positive-pressure, Face-mask Method.—The method finally selected, by process of elimination, calls for the use of an air-tight face mask, with a rubber-bag reservoir for the gases close to the mask. A pressure of from 5 to 12 mm. of mercury had already been decided upon as a result of the animal experiments. This pressure was first de-

*Presented by invitation before the Providence Medical Association, Providence, R. I., December 1, 1919. Approved for publication by the Board of Publications, office of the Surgeon General of the U. S. Army.

termined by means of a mercurial manometer placed in the circuit, but this was discarded as unnecessary when it was found that the required pressure could be estimated easily by the following observation: When the rubber bag is slightly overdistended with the gases, to such an extent that upon full inspiration the seams of the bag are still slightly distended, there is a pressure of from 5 to 7 mm. of mercury.

The positive-pressure method used involves: (1) A constant supply of fresh gases; (2) A constant escape of some of the gas; (3) a slight amount of rebreathing.

The escape of the gases may be through an expiratory valve, although a valve is not absolutely essential, since the mask may be held in such a way that a constant leakage occurs. No air can possibly enter the apparatus at any time when positive pressure is sustained. A slight positive pressure in addition to the gases is unquestionably an important factor in maintaining anesthesia.

The value of positive pressure as a factor in mantaining anesthesia was recognized by the earliest observers. Paul Bert was fully convinced that anesthesia with nitrous oxide could not be maintained without positive pressure, and he had constructed for this purpose an apparatus weighing many hundreds of pounds.

In addition to being an aid in maintaining anesthesia, positive pressure in lung surgery is a very great aid to the surgeon. Willy Meyer was among the first to recognize the great advantage of positive pressure, and he had constructed an apparatus costing thousands of dollars for the regulation of the pressure as needed. Yates[5] holds that "Positive pressure control made examination of the lung and operation much easier and eliminated the necessity for dangerous traction. It offered a simple test of the air tightness of the closure and of satisfactory hemostasis; the necessity for undue haste was eliminated."

Apparatus.—The army apparatus for administering nitrous oxide and oxygen is so simplified and so inexpensive (the whole apparatus weighs not over five pounds) that it may be universally used, not only for lung surgery but for other operations as well.

Oxygen Percentage Used.—This positive-pressure method, in addition to enabling the surgeon to accomplish the best work in lung surgery, allows the anesthetist to give a higher percentage of oxygen, while still maintaining the same degree of anesthesia. With positive pressure we never give less than one part of oxygen to three of nitrous oxide.

Experiments by Cannon and Cattell with the army apparatus show that when three holes of nitrous oxide and one of oxygen is given, both anesthesia and blood pressure are fully maintained; but when the proportion is four to one, the blood pressure gradually falls. This simply means that it is important to give the maximum amount of oxygen at all times with any apparatus that may be used. Usually two holes of oxygen and six of nitrous oxide is the minimum amount, the percentage of oxygen being rapidly increased, as circumstances allow. Both percentage and quantity are important. For the best results it is also important to have the largest sized cylinders, 3,500 gallon nitrous oxide and 1,200 gallon oxygen containers. This relieves the anesthetist of all worry with regard to the supply of gases and the ability to use them unstintingly as needed.

Depth of Anesthesia.—In the laboratory one or two dogs were lost from maintaining too deep an anesthesia. Full surgical anesthesia that is safe without preliminary medication was found to be unsafe with this medication. For these reasons our technique gradually evolved from deep to light anesthesia, and finally to analgesia with unconsciousness. This evolution depended in a very large measure upon the observations and the work of Captain Middleton as medical consultant and pathologist, and upon his observations in the shock ward, upon the radiographic work of Dr. Drane, and most especially upon the experiments of Lieut.-Colonel Cannon. As the morphine was gradually increased, it was found that more oxygen could be given and that the patients were more comfortable and quiet after the operation than when inhalation anesthesia alone was depended upon. The high percentage of oxygen used, in connection with other obvious symptoms would seem to prove that analgesia and not anesthesia is present.* In the system outlined in this paper from 15 to 35 per cent. of oxygen is used.

It happened occasionally in our earlier work that when too much oxygen was given all physiological requirements were met and breathing ceased temporarily, for a half or three-quarters of a minute, the pulse continuing as before and the patient having a pink color. This temporary cessation can be obviated by (1) decreasing the positive pressure momentarily, (2) allowing air to enter the mask, or (3) slightly increasing the amount of nitrous oxide. By using any one of these methods the breathing may be caused to continue normally.

Technique. — Preliminary Medication. — In all chest cases the patient is given one-quarter, three-eighths or one-half grain of morphine, usually three-eighths, hypodermatically, forty to sixty minutes before operation. Rapid or labored breathing, sometimes an important harmful factor in thoracic surgery, is eliminated by giving morphine, and the patient comes to the table in the best possible condition. In only the very young soldier was the respiration so reduced as to be noticeable, but even in his case it was not dangerous. Age seemed to be a more important factor in this particular than the seriousness of the wound. "Lieut. Cattell investigated the influence of morphine in shocked animals and found that it decreased the degree of acidosis which otherwise developed, or prevented its onset, an effect probably due to the influence of morphine in reducing tissue activity." My own views concerning preliminary medication have been clearly outlined.

Narcosis.—The narcosis is started with an amount just sufficient to maintain anesthesia with the Army apparatus, two holes of oxygen and six of nitrous oxide. The mask is held tightly on the face, and the first three or four exhalations are

*It may be stated in this connection that Hewitt proved, very conclusively, that from 5 to 7 per cent. of oxygen with nitrous oxide is sufficient to maintain surgical narcosis. This is the amount now universally used.

allowed to escape through the expiratory valve, after which the expiratory valve is turned off, and part of each exhalation is allowed to escape between face mask and face. The rubber bag is filled to plus pressure, as already described. When the skin incision is made, if there is no movement or indication of pain, the oxygen is increased to three holes, the nitrous oxide remaining the same.

The patient has a pink color, the lid reflex is active, the eye rolling, yet the muscles are well relaxed. From this on any further increase in oxygen is determined by the condition of the patient. If the patient has been gassed, or is still bleeding, equal proportions of the gases may be used, or, in some instances, 75 per cent. oxygen and 25 per cent. nitrous oxide, positive pressure being maintained in all instances. In every case full oxygen is given as the last stitches are put in. The patient now has a very pink color, with pulse and respiration so nearly normal that his true condition may be almost entirely masked. *He should be treated in every instance as a shocked patient.*

Analgesia.—During the operation the patient is in a state of analgesia induced by the morphine, and in *first stage anesthesia* from the nitrous oxide and oxygen. He is safer than if full surgical narcosis were maintained with gases alone, or if a state of analgesia were maintained with morphine alone. Either agent used alone would result in cyanosis, slowed pulse and respiration, and lowered blood pressure.

Analgesia or first-stage anesthesia (with morphine, nitrous oxide and oxygen) may be graphically expressed as follows:

A = Commencement of anesthesia.
A B = Analgesia.
B C = First or excitement stage.
C D = Second stage.
D E = Third or surgical stage—the usual stage in which operations are performed with inhalation anesthesia.
E F = Danger zone.
F = Respiratory arrest.
G = Death.

The safest and best narcosis available to-day for lung surgery is obtained by the combination of the highest possible safe physiological dose of morphine—in our experience three-eighths of a grain, given one-quarter grain forty minutes before operation and one-eighth grain ten minutes later—reinforced by nitrous oxide given with the highest possible percentage of oxygen—fifteen to thirty-five per cent., with positive pressure—given in the easiest and simplest way.

It is *safest* because it is separated from the danger zone by the second and third stages of anesthesia (C to E). The anesthetist, therefore, has twice the leeway or double the time in which to correct or modify the anesthesia if untoward events suddenly occur. In gassed cases, oxygen, 75 per cent., and nitrous oxide, 25 per cent., with positive pressure (5 to 10 mm. of mercury), with morphine as indicated, will induce and maintain satisfactory analgesia in a badly wounded soldier. It is *best* because the blood pressure is maintained at the highest level possible with the given patient.

In no instance were our patients strapped to the table or held by orderlies, the preliminary medication rendering this unnecessary. Only once in thirteen instances was it necessary to give a small amount of ether (1 to 4 drams), two drams usually being sufficient for the entire operation. We never hesitated to give ether when indicated. Since surgical anesthesia with positive pressure is easily maintained with nitrous oxide and oxygen, plus one or two drams of ether, if as much as two ounces of ether per hour is used the anesthesia becomes an ether anesthesia, the nitrous oxide being wasted.

Possible Danger in Method.—If the same degree of nitrous oxide and oxygen anesthesia is maintained when morphine is given as is usual without it (*i.e.* third stage or full surgical anesthesia), shock with labored breathing results. When the proper amount of morphine is given (one-quarter, three-eighths, or one-half grain), and when nitrous oxide and oxygen are used, the morphine eliminates the stage of excitement and analgesia and first-stage anesthesia become synonymous terms.* When given as a preliminary to any method of anesthesia, *the light anesthesia produced by morphine must not be ignored.* In other words, both the amount and the depth of the inhalation anesthesia must be lessened. If the same depth of anesthesia is maintained *with* morphine as would obtain without it, this depth of superimposed anesthesia in itself will produce shock. This constitutes the only danger of the method advocated in this paper.

When three-eighths of a grain of morphine is given hypodermatically the patient's lid reflex under gas and oxygen should be quite active, the breathing quiet and natural, the pulse about normal. Stertor, abolition of lid reflexes, or cyanosis should not be permitted at any time. At the conclusion of an anesthesia conducted along the lines suggested, the patient comes out from the influence of the gases almost as soon as the mask is removed, the analgesia from the morphine continuing for quite a while. The patient can answer questions intelligently, but should be allowed to remain quietly dozing as long as possible.†

Variations in Technique.—The face-mask method with positive pressure may be used without preliminary medication. Inasmuch as with preliminary medication the narcosis comes on sooner and with less forcing of the inhalation anesthetic, and, furthermore, as the margin between complete anesthesia and respiratory failure is lengthened, thus making it a safer procedure, some form of preliminary medication should be used whenever practicable.

The next most powerful analgesic to morphine is ether, drams four, liquid paraffin, drams six, mixed and given by mouth with salt, pepper and lime juice on the bottom of the wine glass and also on top of the mixture. This should be given thirty

*Marshall (*loc. cit.*) states that "shocked patients do not bear morphine well." This conclusion was unquestionably the result of observing men come to the Casualty Clearing Station already heavily morphinized and receiving an additional hypodermic at the station.

†It is customary in certain clinics to give nitrous oxide and oxygen for painful dressings, but the gases are given in such small quantities that the patient groans and complains throughout, the anesthetist assuring him the while that he is not suffering. When the mask is removed the patient remembers nothing that has occurred. This is amnesia, and is not the analgesia referred to in this paper.

minutes before the operation, and may be repeated in ten minutes, if necessary.

The other preliminaries that have a powerful synergistic effect with nitrous oxide or ether are bromide of potash and paraldehyde, two drams of each, given in four ounces of water at about 115° F., by rectum.

It sometimes happens that, through untoward circumstances, one must resort to ether by the drop or some other method for lung surgery. When this occurs the same general principles apply, *i.e.* the use of morphine *as indicated* as a preliminary, and the maintenance of a very light (first stage) anesthesia, just beyond the grunting stage. When narcosis is thus maintained, the patient's lungs are inflated to a greater extent, the patient responding in a measure to the stimulus of the operation and breathing deeply, and the blood pressure is higher than when third degree or full surgical anesthesia obtains. The respirations are always deeper and more regular with a light anesthesia, especially when morphine is used.

The consensus of opinion among surgeons who have used both methods, *i.e.* with and without positive pressure, is against the drop method or any other in which the anesthetist has not complete control of the lungs, inflating or collapsing them as required by the surgeon. Artificial respiration, when necessary, is more easily maintained with the face-mask method than with endotracheal or endopharyngeal anesthesia.

The writer wishes it explicitly understood that he does not consider the technique here outlined to be the best for *all patients* and *all operations*. Nitrous oxide and oxygen, given by an open method (*i.e.* with an extra large face mask), and with one-half to two ounces of ether per hour, is a decidedly better method for abdominal cases where full surgical relaxation is demanded.

Summary of Technique.—1. Hypodermic of morphine sulphate, one-quarter, three-eighths, or one-half grain, with three-eighths as the average dose, forty to sixty minutes before operation.

2. The face-mask method of anesthesia with, preferably, (1) nitrous oxide and oxygen, or (2) ether, air and oxygen.

3. Positive pressure, slight at first, but from commencement of anesthesia, increasing to from five to ten mm. of mercury during operation; then gradual withdrawal as operation is completed.

4. The highest percentage and largest amount of oxygen permissible with regular breathing.

5. First-stage anesthesia, with morphine analgesia throughout.

6. Constant increase of oxygen as operation proceeds (but never to the point of fulfilling all physiological needs, and so temporarily arresting respiration).

Clinical Conclusions.—The value of the method herein detailed has been summarized, from the clinical point of view, by Cannon[4] as follows:

1. Three months' active experience in the clinical application of these experimental data proved specifically, reduction of the incidence, degree and extent of pleurisy.

2. Prevention of contralateral collapse.

3. Practical elimination of pneumonia as a complicating factor.

4. Operations performed under analgesia rather than anesthesia, permitting successful surgical intervention in otherwise hopeless chest wounds, and eliminating to a large degree the anesthetic factor in shock.

A CASE OF MIXED NEUROSIS WITH SOME PARAPHRENIC FEATURES.

By MARY K. ISHAM, M.D.,

NEW YORK.

THE history of this case, only a part of which is here reported, is rich in psychic mechanisms now fairly well understood, but in order not to interrupt the continuity of the patient's disclosures, I shall postpone discussion of them until the latter half of the paper.

The patient, married, aged 30, a violinist and musical composer by occupation, was of Russian Jewish parentage and the eighth of ten children. He complained that he could not live at home with his wife, because he was afraid he would harm his small son and only child, aged fifteen months. He said the baby's crying nearly drove him crazy, although it was a very good and healthy child, and cried no more than other children. On the other hand, when it was quiet, he was worried, for fear something ailed it. He would then pinch and poke it to see if it would cry, and when the normal response was made, he was beside himself. He *knew* the child was all right, and yet he could not control these feelings. This was the trouble which drove him to consult a physician, but he suffered from other conflicts, all of which he thought would be injurious to the child.

He said his real trouble began when he lost himself in Paris while studying music there when he was seventeen. This loss of self happened one afternoon as he entered his gloomy room after a walk. The walls were so dull, like a prison. He looked at himself in the mirror and got a view of the right side of his face, which looked drawn and pale, saggy, worried, and lonesome. He didn't feel right and was homesick. There was something different about him, it was not clear to him what. This happened about ten months after he arrived in Paris. The feeling kept up for about a year, and has lasted more or less ever since. When playing in company, it used to come over him that he was not himself, that he was falling to pieces and could not hold himself together.

Going further back in his history, he told of falling off a bicycle about a month before he left for Paris. He fell on the right side of his face, was dazed from the fright, and stayed in bed a week or two. He did not feel quite right after that and his whole life in Paris was a disappointment.

Before he went abroad he met the girl who later became his wife. It was a case of love at first sight. She was a fine pianist and played accompaniments for him. When his family found out that he intended to marry her, they interfered. When he reached Paris, they worried him into such a state that he became indifferent to his sweetheart and quarreled with his mother. His father wrote him letters about money troubles and hinted that he should put a wife off his mind. Even his cousins wrote him not to correspond with his sweetheart.

During that time he was torn by many indecisions as to whether he should (1) follow the advice of his relatives or carry out his own plans with regard to marriage; (2) go home or stay abroad and spend the money which his family could ill afford; (3) follow advice to go with women of questionable character or stay away from them; (4) yield to adolescent masturbatic fantasies and indulgences or try to control himself absolutely. Controlling these practices resulted in seminal losses during sleep which frightened him dreadfully, as he thought that such losses would be the cause of some sort of injury to his children.

At the same time he was in a very depressed physical and mental state resulting from hunger, cold, and lack of sleep. He had no comforts and his esthetic sensibility was constantly hurt. He was very lonesome and did not make friends, because he was too poor to go with those he liked. He played around at restaurants and hotels, and once after playing at a ball in very cold weather he was found freezing in the street. At this period of his life, walking was his only recreation. While taking long walks, he made many resolutions about changes in his life, and one afternoon he decided to give up his sweetheart as his family demanded, save every penny except for bare necessities, and control all sex thoughts and desires. It was after one of these afternoon walks, that he entered his room, gloomy and empty, looked in the mirror and saw himself so strange and different. Life and its cruel hardships seemed hopeless.

Coming back to the time of the first consultation, he said that he had recently had a bad quarrel with his wife, the girl about whom he had had so many conflicts and to whom he had been married three years. As she took entire care of the baby herself and had many household duties, it was almost impossible for her to see him every day promptly at the time he set. "It was raining and she could have come to see me earlier," he said. "Instead, she came later. Before she explained, I got angry. We are such unlucky people. We create our own trouble. She is very slow about telling things. There is a great misunderstanding between us. I can't understand why she came late. I imagine she is not interested. I'm very quick. I walk fast and talk fast and think fast and don't get exhausted quickly. But there is always a cloud on my system. The baby is always on my mind. It sounds in my heart. Rain has always depressed me, but since the baby came, it is worse. These things are awful. Sometimes I have a peculiar day-dream. I get away millions of miles. It is so nice, so fine at that moment, but I cannot recall it. It is nothing of this earth. It is a constant sub-conscious hearing of scores. My hearing is for absolute pitch. I can tell any note. My ears and eyes are perfect."

During one visit he played selections from his new overture which he had brought with him. They were very beautiful, suggestive both of Chopin and Grieg, but distinctly not an imitation. He was not pleased when I told him this. He said he did not admire Chopin's music. It was sickly and effeminate. He preferred something masculine, virile, strong, massive, heavy, and substantial, like the music of Bach, Wagner, and some of Beethoven.

"I hear everything within me," he said. "My inner hearing is always ringing. When my baby cries, I get rigid in the back and under the ears. When I began to annoy the baby, I lost my mind. Something was coming over me that was not natural. At the time the baby was born, I was playing four times a day and worked with a personality I did not like. This Ruffini wanted to mislead me, to boss. As soon as I met him, I felt sick. I dreaded and disliked him. I always felt a load on my spine when with him. He affected my whole mind. We used to have quarrels. I once played a little something. He said, 'Don't play with so much feeling. It isn't necessary.' That man is all for business. Gambling and stocks are his mania. He used to criticise me about my quietude. But when he was pleasant, I felt worse. No matter how friendly he should be to me, I couldn't stand him. Very masculine and aggressive. I hate that type. There is something horrible and psychic about him. It was just my playing he cared for. He does not care for anybody. He has a dominating spirit. He says he has been in many fights and shows his muscle. He likes to torture people."

"If men were of my tastes, I would like men better, but I enjoy myself more with women, because they understand me better. My wife and I are not attracted sexually. It is more of a friendship. Her love is not of the physical kind. It made me very happy before marriage to think she was so spiritual, but she did not understand me at all. She gave me a nervous fear. I wanted my wife to understand me. I would get absent-minded from emotion. When a person gets emotional, he wants to express himself. But he is free from passion. Such emotions are fine, ecstacy. Marriage should bring passion and emotion together, but it does not . . . . . Sometimes my wife aggravates me. She has the worst temper I ever experienced. If people are continually getting into quarrels, they would better be separated. My wife comes to see me every day. She could come earlier. She never explains. If I ask her why she is late, she always answers 'It was the baby.' I'm very punctual myself. I like things to be exact. If my wife would come earlier an hour or so, I would feel better. Doctor, why *doesn't* my wife come earlier?"

I have not indicated the number of times the patient complained about his wife coming to see him late. He would twist around in his chair impatiently, get excited, and ask me over and over, "*Why* doesn't my wife come early? Why is she so slow? Why doesn't she try to explain before I ask her? Why is she so indifferent?" He was quite unaware of how these worries occupied him as much as did those about Ruffini and the baby.

As a matter of fact, his wife was very eager to do everything she could to help him and ease his mind. She was not always late, and when she was, it was on account of unavoidable delays at home. There was no special reason from a superficial point of view why she should come to see him at one time more than another. But this anxiety on his part had a deeper determinant. It was disclosed finally that he was not really worrying about the promptness with which she met the daily appointment, but about something else, the existence of which both were aware, although not understanding its relation to their unhappiness. He suffered from *ejaculatio praecox*, and his wife was frigid. His wife had told him that he was too impetuous, but neither had spoken to the other about the matter, because they never discussed such things, and did not think they made any difference. They accepted such maladjustments as belonging to the ordinary and irremediable episodes of human life and dismissed them from conscious thought. He had displaced the anxiety arising from only partially satisfied libido upon an incident of quite innocent appearance having a similar disturbance of time relationship and mutual adaptation. There were still other determinants for the selection of this particular object of displaced anxiety, which I shall mention later.

The day after this discovery, he brought his wife with him. It seemed quite wonderful to her that something had been found which had always bothered her considerably, but which she thought was wrong to speak or even think about. When they adjusted this matter, his pathological anxiety about his wife's punctuality ceased. I did not explain to him the relation between the displaced anxiety and its original source, because after the adjustment was made, no more discussion was necessary. He simply needed some medical instruction about sex functioning,—a matter upon which he had never properly been informed. He did not again complain of his wife being slow or indifferent, and several weeks afterward, when I asked him if she was still coming late, he answered, "Oh! I never worry about such things. Such trifles never worry me," and was quite unconscious of how he had been fussing about the matter.

With this worry eliminated, he was able to talk more freely about his obsession in regard to his child. During the adolescent period when away from home and forlorn in Paris, he was blocked in the quest of his real love object by a respectful attention to parental authority, and as a substitute for his deprivation, he had reverted to fantasy which led to masturbatic practices. As we have seen, he had long been afraid that there would be something the matter with any child of his on account of his adolescent indulgences. Controlling these had caused seminal emissions during sleep which frightened him. He thought that such losses meant injury to his offspring. He worried later because he was unable to relate the child to himself. It looked like the other personality which he had lost in Paris. He could not connect his present self with the child.

In addition there was a peculiar relation between himself and parents which he could not understand, something within him in regard to this that frightened him. When he lost his personality, he thought about his parents. There was no complete understanding between them and him. When he thought of his mother whom he resembled he always envisaged the shape of her face. There was great trouble between him and his parents from the time he knew his wife. They had nothing against her, but thought he ought to marry a rich woman. He hated his father, brutal, indigent, lazy, and selfish. All the older children had been put to work as soon as they were able in order to furnish support for the family, while the father sat idly at home and did nothing. He hated his father, but had never been able to effect an emotional independence of him, for he still retained an infantile fear of him. In fantasy, he castrated him.

The analysis showed that the patient was making a phallic symbol of his small son who represented a castrated organ or lost virility. The pinching and poking were tests, and when the child cried, *i. e.* showed virility, it reminded him of adolescent seminal emissions, concerning the meaning of which he had been ignorant and anxious with a sense of guilt. When the child was not crying, he feared that it was deficient, impotent. He had to test it in order to assure himself of his own potency. The compulsive tests were also modified expressions of repressed cruelty, developed from unabreacted hatred against father, first violin teacher, and Ruffini. His relation to his first teacher of violin will be explained later.

The fact that the child stood in his mind for his lost, not his real, manhood explains why he could never effect a satisfactory relationship between it and himself. His anger at his wife's answer, "It was the baby" when she came late, is now explicable when we consider the symbolism attached to his baby. And his wife's slowness in comparison to his quickness touches the same complex at another angle, for his extraordinary quickness of reaction was only a symptom of an underlying inability to postpone and integrate temporary and partial pleasure reactions into more mature experiences.

The right side of his face had been cleverly selected as a defense wherein to hide the feeling of reproach generated from his unsatisfied libido. The excuse for his selection was the fall from the bicycle and an injury to the right side of the face. It was also fitting, because of its connection with a fall. Preceding, during and after the illness resulting from the fall there had been the same moral sense of fall pursuing him right up to marriage, emerging soon afterward, and returning with greater force after birth of his child. When the libido became more properly occupied both through adjustment with his wife and comfortable, normal fixation upon his child, the anxiety and reproach cleared up, except that part which belonged to the troublesome homosexual component and its sublimations, to be discussed later.

The way his face appeared to him was also the way he regarded his own personality. His face resembled that of his mother, and in its wrong appearance he wronged his mother—his real mother, his mother nature, and his moral self developed by the mother teaching—with whom he

was identified and therefore not psychically separated. His regression to the image of his mother's face in times of conflict was a way of exressing the desire to return to the comforting presence of his mother and to a life with mother nature not so exacting as the present, to get close to the face of nature. There were other mother identifications, among which was the narcistic dependence on the mother, treating his wife as his mother and childishly expecting a mother's care from her, and his slavish attitude toward his father, although consciously he rebelled against him. It is impossible to go into all these different processes. They ceaselessly work into each other and a sketchy objective view must necessarily break them up into dead fragments.

We have seen in some of the material presented, as there is also in much not noted here, that when the patient speaks of his musical preferences for other composers, he likes the virile, massive, heavy, dominating. He is then expressing the wish for a love object of his unconscious and sublimated homosexual component, but when defensively entering the every-day world of actual contact with men, he denounces this type and veers toward the quiet and refined men with whom he identifies himself. His own creations are of an ethereal, superrefined quality, himself sublimated into music. Most of his dreams and the terms he uses in ordinary conversation regarding men show an unconscious attraction to those approaching the sadistic type. This tendency dates from experiences with his first violin teacher, who was very stern, domineering, and almost cruel, but whom he liked as well as feared. He took lessons from this teacher before he was seven years old. Before this time he was tolerably happy, although he lived in a very sordid and disgusting environment. The teacher was very rough, cranky, and irascible. "He would hit me," the patient said, "and I was afraid of him and dreaded him. I didn't begin my career with the right man. This trouble is right in my blood. Sometimes I used to go and take my lessons in thunderstorms. I was afraid and would get depressed." While discussing this period of his life, he dreamed *of an approaching storm. The clouds moved very fast. It was taking place at night. He had a peculiar dread. Everything was so light. He was always looking out of the window just as a child does before an approaching storm.*

The anxious fears during the thunder-storms in the lesson hours with this teacher are carried over into the present, and by a mechanism similar to the conditioned psychomotor reflex, he is unhappy during rain without thunder and when practicing music without the original teacher. His dread of thunder-storms goes even farther back than this to days of infancy, when there was a rumbling of the bowels and desire to evacuate at night, angry disapproval of his father and a light in the room. The looking out of the window means a wish to escape outside. The physical discomfort of a sense of weight and strain on the lower part of the spine, the anxious dread that the storm will break (that the feces will come thundering down) arising from intestinal uneasiness and fear of punishment from the father, all these had been carried along to other situations of subordination in the presence of domineering and harsh personalities who reminded him of his father. The old anal urge with its accompanying anxiety, hope, love, hatred, and fear of punishment determined the reaction toward his homosexual object. It was a childish affect toward a father image, first in the shape of the violin teacher, and then through several transferences (which I have not mentioned) until culminating in his enslaving attraction toward the fascinating and terrifying Ruffini.

The day after spending an hour at my office in talking about Ruffini, he brought the following dream. *A man was running after my wife. She said she was going to commit suicide and I couldn't stop her.* This dream nicely illustrates the mechanism of projection and displacement upon his wife of an unconscious homosexual wish. His wife is being pursued by a man by whom he himself wishes to be pursued. In addition it shows a former wish, during an enhancement or temporary rising of the homosexual impulse, that his wife would put herself out of the way without any responsibility on his part. That he secured a position with Ruffini, even though he knew, or thought he knew, what sort of a person he was points to the trend of his creative urge at the time. He had heard of him for twelve years. He greatly exaggerates this man's character, however, according to the customary over-estimation of love and hate objects.

There is a cyclothymic swing between the depressive feeling of unreality and that of exaltation and well-being. His excessive constraint and backwardness, fear of disintegration of personality, of not being able to hold himself together belong to a paraphrenic make-up. On the other hand, he swung to the opposite, hysterical extremity in attacks of dreamy states of ecstacy, dramatic imitation of the persons who annoyed him, and great suggestibility. We have already discussed his anxious and compulsive states.

The many mechanisms revealed by analysis in this, or any case, are impossible to manage satisfactorily in a short article. The fact that we have mentioned them by name must not be mistaken as an attempt to classify the patient in a depreciatory category. Calling names does no good. These terms are simply mediums of expression and apply to every one more or less.

The analysis was by no means complete at the end of the twenty-second session, but because the symptoms for which the patient came to be treated were cleared up, and for other reasons, financial and vocational, he stopped coming. He was rid of the troublesome obsession regarding his son, had made a better adjustment toward his wife, and obtained an insight into his feeling toward Ruffini. He afterward secured another position, and was more free to work on his musical compositions.

135 West Seventy-ninth Street.

Ambulatory Cases of Lethargic Encephalitis.—Morax and Bollack state that patients who are going about as usual have been found to be suffering from this malady through the ocular disturbances of ptosis and diplopia. Anisocoria may also be a symptom, while a fourth symptom is paralysis of accommodation. Chauffard has seen sudden ptosis in an ambulatory case along with tendency to somnolence. The type of case was mild. Lortat-Jacob saw in an ambulatory subject diplopia and nystagmus.—*Le Bulletin Médical.*

ENCEPHALITIS EPIDEMICA (MISCALLED LETHARGICA), WITH SPECIAL REFERENCE TO DIAGNOSIS

By TOM A. WILLIAMS, M.B., C.M.,

WASHINGTON, D. C.

PREMATURE generalization on a basis of slender experience, and want of neurological knowledge, are rife concerning this disease. The name given it is a glaring instance, for the cases without lethargy are very numerous. It would be as justifiable to give the name "neoplasma cerebellaris" to cases of tumor of the small brain because these are so frequently characterized by torpor. The name "lethargica" might as reasonably have been applied to dementia paralytica. Of enteric fever, this concept showed itself in the name "typhoid." Typhus fever has been named similarly. As a matter of fact disordered feeling and impaired thinking are perhaps as frequent as is lethargy in the course of acute encephalitis.

Of ocular symptoms similar criticisms may be made. Histological examinations show that the disease is not focal, but diffuse. There is a universal invasion of the central nervous system by an infection, the reaction to which is a perivascular diapedesis of mononuclears. This impairs the function of the nerve elements, possibly by ischemia. If this is of only short duration recovery of function occurs when the circulation is reestablished, but after a period comparatively short, necrosis supervenes with the resulting permanent loss of function, as a regeneration in the central nervous system does not occur. In the more severe and rare cases, hemorrhagic exudation may take place. If this is large, or if in a nuclear area, it may cause a destruction of tissue showing itself by permanent impairment of function. As the ocular nuclei are very small, are concentrated in restricted foci, and as they perform delicate functions which cannot be supplemented by other organs, a very slight assault will show itself symptomatically. That is why the affection of these nuclei is so conspicuous clinically when it occurs.

On the other hand a degree and extent of ischemia sufficient to impair the function of a small nucleus scarcely affects noticeably a large area like the centrum ovale. It even may fail to affect symptomatically such an organ as the precentral cortex, of which a considerable lesion may produce few symptoms, a familiar experience in the course of apoplectic hemiplegia.

However, *motor cortex syndromes* do occur because of acute encephalitis. In older people these may be very difficult of diagnosis, as in the case of a woman recently seen where a sudden aphasia while telephoning was attributed with reserve to the vascular inadequacy of late middle life. Encephalitis was not even suspected until three weeks later, when general torpidity intervened and another physician had no difficulty in making the diagnosis, which, however, proved inaccurate, as at death a month after that a frontal neoplasm was found.

When it is the *psychological functions* which only are impaired, the diagnosis is still more difficult. Such a case was that of a man in the 40's who was discovered in his embassy at midday very much excited because of a sudden loss of memory which was almost complete when I saw him two hours later. The agitation he showed was natural under the circumstances, but the alarm it had created among his colleagues was quickly allayed when they observed how easily the patient was managed by me. The next day the amnesia had completely disappeared, the patient remembering perfectly the most difficult tests. Only a general restlessness remained, lasting for a week or two without any torpidity.

Insomnia is a frequent symptom in cases of this kind. It is often of an agitated character and may be attributed to the uneasiness caused by disturbance of function of the thalamic region which produces an affective disquiet, not at all due to psychological situations, and therefore not more than temporarily amenable to psychotherapy.

Only by its acuteness does the disease symptomatically differ from the granulomata which affect the central nervous system, in particular the form of syphilis known as dementia paralytica. This is easy to understand, for pathologically both are due to mononuclear invasions of perivascular distribution. The individual access need not differ in the two diseases; only the course does so.

To some, lymphocytosis of the cerebrospinal fluid has appeared an easy road to diagnosis, but this is not present in all cases, although it is generally so. It must be remembered, however, that it also occurs in disseminated sclerosis, another inflammatory disease occurring acutely, although of chronic course with exacerbations. I can conceive of cases where the differential diagnosis would not be possible without prolonged observation.

The colloidal gold curve, formerly supposed to be characteristic of paresis, is found frequently in encephalitis, but in these cases the Wassermann reaction is always positive in the latter disease, and never so in the former.

Lymphocytosis in mumps has led to an error of diagnosis, and could readily lead to error in tuberculous meningitis also.

To poliomyelitis this disease is pathologically an almost complete homologue, the latter, however, being often more intense pathologically speaking, as shown by the extensiveness of the exudates, and their frequently hemorrhagic nature. This accounts for the permanence of the results in so many cases. Tilney's case of poliomyelitis with prolonged somnolence has an encephalitic aspect.

Diagnostically between the torpid cases of poliomyelitis and the cases of encephalitis with paralysis, a decision can be made only tentatively in the initial period. This is particularly so in encephalitis with muscular atrophy.

Differentia are only tentative, too, in cases of encephalitis where the conspicuous symptoms are spinal segmental. Ascending or descending radiculitis lasting several weeks has characterized these. They resemble the meningitic form of poliomyelitis, and, except by their acuteness, they are not distinguishable from the lightning pains of tabes, except when the patient has well marked other signs of syphilitic radiculitis, such as loss of reflexes and anesthesia, more particularly of the attidude sense, and unless the serological reactions are positive.

This pseudoradicular syndrome probably arises endogenously, the posterior root zone within the spinal cord being progressively irritated by inflammatory invasion. One can hardly postulate a progressive meningitis as an explanation. I have, however, noted the Brudzinski sign in one case and the Kernig sign in two, and these are indicative of meningeal irritation. No post mortem of the radicular form has been reported, all five cases of Pardee, who has described it, having recovered.

Xanthochromia of the spinal fluid has occurred in two cases I have seen. In one of these there was also edema of the optic papilla. The yellow color of the spinal fluid in these cases must be due to absorption from an encephalitic hemorrhage. The diagnosis from a compression syndrome is of course made by the absence of level symptoms referable to the spinal cord.

Papilloedema may not be so rare when more consistently looked for.

From hysteria the diagnosis may be quite difficult when no physical signs have occurred, and flighty behavior is the only symptom; for patients whose cerebrum is impaired show an exaltation of suggestibility. This is a familiar truth to those who deal with states of mental confusion from intoxication. Encephalitis, however, resembles these latter in that there is an impaired fixation of attention, and the ductility, as regards any particular stimulus is evanescent; while in the hysterial the suggestion tends to be tenacious. Further, hysteria should never be diagnosed by exclusion, but only after the discovery of the initial suggestion which has determined the hysterical behavior.

The erroneous doctrine that physical disturbances can be of hysterical original must not be allowed to influence the clinical diagnosis in the study of these cases as has occurred in a local instance recently. The weak suggestibility due to encephalitis was the foundation of an erroneous diagnosis of hysteria in a case recently seen in North Carolina, even although lethargy was present and partial ptosis had occurred.

The most difficult diagnosis of all is from the mild acute psychopathies, with or without delirium. In these cases the diagnosis can be made only by watching the course of the disease, or by finding lymphocytosis of the spinal fluid.

OSTEOMALACIA: IS IT A RARE OR RATHER COMMON DISEASE?*

By WILLIAM H. DIEFFENBACH, M.D.,

NEW YORK.

ROENTGENOLOGIST TO THE BROAD STREET HOSPITAL, COMMUNITY HOSPITAL, ETC.

At my service at the Broad Street Hospital, patients suffering from osteomalacia have been observed with varying frequency during the past few years so that a recent article in the *British Medical Journal* (Oct. 18, 1919), quoting Fromme of Göttingen, who described an endemic of osteomalacia in his city particularly interested me. The patients were almost exclusively young males aged 11 to 18. Their work was heavy and they complained of pain in the knees and hips, tiredness on slight exertion, and inability to do strenuous work. *X*-ray studies of the femur and tibia showed rarefaction of bones which in places disappear altogether. There was also a striking widening of the epiphyseal line and in eight cases there was spontaneous fractures somewhat above the epiphyseal line with impaction of the thin diaphysis into the comparatively wide epiphysis. In the case of one female patient the bones of the pelvis showed the above changes and her gait was characteristic of osteomalacia. Other manifestations of bone softening seen in some cases were coxa vera and pes planus.

The causes underlying this condition were stated to be due to underfeeding due to the war, lack of phosphoric acid, as found in cheese, butter, milk, fish, meat, eggs, and rice. The rarefaction of bones is also referable to calcium deficiency. The occurrence of the endemic toward the end of winter, when a shortage of vegetables prevailed, also suggests vitamine deficiency as a factor in this disease. Infectious diseases, notably influenza with endocrine abnormality, may also have influence upon this disease.

Similar endemics are prevalent in Vienna, where hundreds of patients are reported suffering from osteomalacia. During the past few years we have been meeting with an increasing number of cases of osteomalacia and the generally accepted textbook statement that this disease is rather uncommon must be modified.

Patients referred to our *x*-ray and electrotherapeutic service for chronic rheumatism and arthritic conditions, when carefully studied with the *x*-ray, were in a surprisingly large number of instances found to be sufferers of osteomalacia. Sometimes the lesion was localized, but in a fairly large percentage of patients the osteomalacia affected much of the osseous system. The frequency of these cases has been such that whenever a particularly chronic or stubborn arthritic lesion is encountered, a careful study is made to eliminate osteomalacia.

The pathology of this disease is described as a degenerative osseous change with softening and bending of bones with atrophy. Frequently spontaneous fractures occur. The bones become shell-like, the medullary canal increases in size and fatty and colloid degenerations are met with. Calcium salts of the bones are absorbed until nothing but a very thin outer hull remains, which readily fractures. During pregnancy this absorption is due to the demands of the fetus, and the desirability of supplying foods rich in lime during this period is strongly indicated.

While the danger of oseomalacia during pregnancy has been realized and noted for many years, other characteristic symptoms of the disease during other periods are frequently overlooked.

Nervous and mental depression during the climactoric frequently has, as a basis, calcium deficiency, and osteomalacia is frequently associated with it. This points to gonad-ovarian deficiency. Patients who complain of insecurity of limbs, so that they must fix their eyes on the feet in order

*Read before the Academy of Pathological Science, March 26, 1920.

to walk, are usually found to be osteomalacic. This occurs frequently among the aged, when through osteomalacia the bones degenerate and bend and the stature diminishes. Changes in stature of three to four inches within six months have been noted due to osteomalacia.

Very often the lazy man's diagnosis of rheumatism or arthritis is made in cases of ill-defined pains, weakness and insecurity of the limbs, when careful investigation shows osteomalacia as the basic lesion. The rheumatic patient who does not respond to medication within a reasonable time and has had careful examinations in regard to focal infection and autotoxemia should be examined for osteomalacia, and it will surprise the investigator to notice the frequency of the complication. In our studies we have particularly observed this osseous degeneration in the bones of the lower extremity, the pelvis, the vertebræ, and the thorax. In the pelvis, deformities are often encountered which render pregnancy hazardous. The characteristic gait of osteomalacia is the short, unsteady step, with bent back and the head bent forward.

A so-called rheumatic patient in whom a reduction in height is noted is usually found to be osteomalacic. Pain in the tarsus frequently treated unsuccessfully for flat foot, is often due to osteomalacia. In some cases of osteomalacia, diabetes has been a concomitant and this has drawn attention to the possible endocrine basis of the disease. As the parathyroid glands are now believed to preside over calcium metabolism, as the thyroid presides over iodine metabolism, there is some reason to look for parathyroid abnormality in this disease. Adrenal deficiency is also believed to be a factor in many instances. The temperature is usually nonfebrile and the blood-pressure is below normal.

The urine in these patients almost invariably shows excess of earthy phosphates, and frequently glycosuria is noted. The white line of Sargent was elicited in several instances. A typical case which was treated on my service was referred for *x*-ray examination of the hip. Typical osteomalacia of the femur, pelvis, vertebræ, and chest was noted. The patient had lost three inches in height within one year and had run the gamut of rheumatic remedies for ill-defined pains in the back and joints. She could not walk without fixing her eyes on her feet and even then her gait was unsteady and short. Tests for the reaction of degeneration and Babinski were negative and the Wassermann was negative. The patient was placed in bed, received foods rich in vitamines and lime and phosphorus, and was rayed daily with the alpine ultraviolet lamp for 10 to 15 minutes over different parts of the anatomy. Calcium lactate gr. v, t.i.d. was given, also phosphorus in dilution. In view of the possible special endocrine origin of the disease, parathyroid and ovarian tablets were also given, the former in 1/10 grain and the latter in 1 gr. tablets once a day.

The rest in bed, the actinotherapy, and possibly also the medication gave the patient much relief during her hospital stay. She has recently reported another setback and I have referred her to one of our colleagues from out of town for further treatment. Whether the disease can be checked in an advanced condition such as this one is doubtful, but it seems plausible to assert that early manifestations should respond to diet, fresh air, actinotherapy, and endocrine remedies, particularly suprarenal, ovarian or testicular, and parathyroid.

Whether these glandular remedies should be used singly or in combination or alternation depends in our judgment upon the special symptoms. If the white line of Sargent is marked and the climacteric is present, both adrenal and ovarian (corpus luteum) tablets would seem to be indicated. If no special indications present, parathyroid for its favorable action in calcium deficiency would seem to be called for.

This short study is brought to your attention, as it is the belief of the writer that a great many lesions of osteomalacia escape unnoticed until they become chronic and are then relegated to chronic invalidism or the symptoms are attributed

to advancing age. Very often the lesion is first diagnosed when spontaneous fractures occur. As a matter of fact, many chronic rheumatic or arthritic patients will be found suffering from osteomalacia after careful roentgenological and clinical examinations. There is hope for improvement in these patients if the basic cause is removed or ameliorated.

Résumé and Conclusions.—1. It is contended that osteomalacia is not an uncommon disease, but is simply not recognized, as a rule, until spontaneous fractures call attention to the osseous lesion.

2. Osteomalacia simulates rheumatic and arthritic conditions and should be carefully excluded in the above lesions.

3. Aside from the Roentgen diagnosis, which is typical and readily disclosed, there are sufficient clinical manifestations to diagnose the lesion in early stages.

4. These are the characteristic short, unsteady gait, with bended back and lowered head, the indefinite or vague rheumatic pains referred to dif-

ferent articulations, the excess of earthy phosphates in the urine, the frequency of the white line of Sargent, and, as the disease continues, the diminution in height due to the atrophy of bone or bending of the femur and other long bones.

5. The etiology, judging from the endemics encountered in Central Europe, points to under nutrition or improper nutrition with deficiency of lime, phosphorus, and vitamines.

6. Suprarenal, parathyroid, and gonad deficiences are also noted in this lesion. Whether these are reflexly due to the above nutritional defects or are primary in character, remains to be determined.

7. Treatment by means of rest, actinotherapy, diet, and endocrine products, especially in conditions not too far advanced, will be effective.

50 Central Park West.

CHRONIC PULMONARY CONDITIONS SIMULATING ADVANCED TUBERCULOSIS

By WILLIAM NARINS, M.D.,

NEW YORK.

ASSISTANT ATTENDING PHYSICIAN, TUBERCULOSIS CLINIC, GOUVERNEUR HOSPITAL.

Among the many cases of lung disease treated at the Gouverneur Tuberculosis Clinic in the past ten years, the following have been selected for this report as illustrating the difficulty often encountered in the diagnosis of pulmonary tuberculosis.

It has been asserted by the general practitioner that the chief difficulty lies in the diagnosis of the early or incipient case, with few or no chest signs, while the more advanced cases,—that is in the second or third stage,—are comparatively simple and are easier to diagnose. The cases here presented illustrate some of the difficulties of diagnosing those with many chest signs, and demonstrate that it often requires a much longer period of observation to arrive at a correct diagnosis in this latter group, than in the early or incipient class. Of course, the finding of tubercle bacilli in the sputum will at once clear up a doubtful case; but many cases regarded as tuberculous do not show the bacilli in the sputum (closed cases) at any time in their course, even on repeated examinations, particularly those of the chronic fibrous type; and it is this group which is most troublesome to distinguish from other chronic thoracic conditions which run a protracted course, with pains, cough, loss of weight and appetite, and general debility strongly simulating tuberculosis.

After watching these cases for a long time,—and some of them have been under observation for eight years or more,—one should come to some conclusion as to the underlying cause of the trouble with a reasonable degree of certainty, but it is the opinion of the writer that in some instances the actual diagnosis can be ascertained only by autopsy.

If one remembers the frequency with which tuberculous involvement of the lung is found, on autopsy, in cases dying of other causes, one hesitates considerably in declaring that any patient with suspicious lung signs is not tuberculous, especially until all the means at ones command, for diagnosis, have been exhausted.

Case I.—Chart No. 1756. Female; Russian; aged 37 years. Patient was admitted to the clinic November 22, 1909, with a history of having had pneumonia nine years previously; had always coughed. Her present illness began nine months ago with cough and moderate hemoptysis, pains in the chest, occasional night sweats and moderate expectoration; lost no weight, rather gained some. Temperature on admission 99.6° (by mouth), pulse 110, respirations 24. She was a short, stout woman, being only 4 feet, 9¼ inches and weighing 158 pounds, and did not give one the impression of being tuberculous. Physical signs: Resonance impaired at left apex and infraclavicular space. Breathing at apex bronchovesicular and tubular, almost cavernous below the clavicle, where a number of crepitant and subcrepitant râles were heard. Scattered râles of all kinds heard throughout rest of right chest. Heart: No hypertrophy or murmurs. Blood pressure, 120. Sputum negative. Urine, albumin and sugar, negative. An *x*-ray of the chest, taken later, showed pulmonic fields of even size but unevenly illuminated. Considerable infiltration throughout the right chest; left side shows infiltration at root and central portion.

The diagnosis on admission was pulmonary tuberculosis, stage III. If the signs in the patient's chest were caused by the tubercle bacillus she was certainly entitled to that diagnosis; the night sweats and hemoptysis were suggestive of it. At the present time we are more hesitant to make a diagnosis on the first examination, preferring to keep the case under observation in the clinic and to be guided in our diagnosis by subsequent observations, but in our early days of enthusiasm, we did not hesitate to make a diagnosis on the patient's first visit to the clinic.

This patient continued to do well under treatment and steadily gained in weight until June 8, 1911, when she weighed 172 pounds. The physical signs in the chest were nearly always the same, and the sputum was negative on periodic examinations. About June, 1913, sugar appeared in her urine, she began to lose weight and feel badly, cough and expectoration continued with occasional hemoptysis. Her weight went down to 150 pounds, and she frequently ran a pulse and temperature. The complicating diabetes made the case more difficult. About this time also her breath assumed the odor of a pulmonic abscess, possibly from purulent collection in a bronchiectatic dilatation, and she was now generally regarded as a case of bronchiectasis, in which diagnosis Dr. Mannheimer, who was called to see her in consultation, agreed. We continued to treat her until June, 1916, when she was discharged as a case of bronchiectasis and diabetes and not tuberculosis.

This case illustrates the difficulty in diagnosing some of these chronic lung diseases, as in many respects history, symptoms, and physical signs strongly resembled a case of chronic pulmonary tuberculosis, but the continued absence of tubercle bacilli raised a doubt, that was substantiated by prolonged observation, and it has taught us to be a little more wary of making a diagnosis on one examination.

Case II.—Chart No. 2927. Male, Russian, age 57 years. A presser by trade. Admitted to clinic August 17, 1912. Previous history unimportant except for a chronic winter cough for several years past. Present illness dates back to last winter's cough, which persisted until time of admission. Physical signs: Impaired resonance at apices, with wooden box-like resonance over rest of chest, which was barrel-shaped. Breathing labored and of poor vesicular quality over entire chest except the left upper lobe, where it was harsh; musical and mucous râles scattered over entire chest, more marked on left side. Heart: Hypertrophied downward and to right. Epigastric pulsation, no murmurs or thrills. Temperature 98.4°; pulse 92; respirations 20; blood pressure 110. Sputum negative on repeated examinations.

A diagnosis of chronic bronchitis with emphysema was made, and the patient was allowed to come to clinic for treatment and further observation. His condition remained the same with but slight variation as

to weight, temperature, and pulse. Cough was the most troublesome symptom. Periodic physical examinations showed but little alteration in chest signs, and on May 28, 1913, he was discharged from the clinic as "not tuberculous." On December 19, 1918, more than five and a half years after being discharged as not tuberculous, patient was re-admitted to the clinic, having lost some weight; temperature 99.4° (mouth); pulse 110, and respirations 50; the physical signs in the chest were almost identical with those of previous examinations, but a sputum examination showed tubercle bacilli present. He seemed to be in bad condition, being greatly worried over the loss of a son, killed in the war, and died on December 31, 1918, about two weeks after re-admission to the clinic.

The question in this case is, Did the man have tuberculosis at the time of his first admission, or did he acquire it later? The physical signs were typical of chronic bronchitis and emphysema, and the repeated negative sputa would tend to confirm this view; yet it is possible for the two conditions to have co-existed, the chronic bronchitis and emphysema masking and obscuring the tuberculous infection which may have been quiescent, becoming manifest only under the added strain, mental and physical, of this man's grief at having lost his son. The true condition must remain in doubt, but it behooves one always to bear in mind the possibility of tuberculosis co-existing in an apparently uncomplicated case of chronic bronchitis with emphysema.

CASE III.—Chart No. 3163. Male. Age 42 years. Admitted to clinic July 18, 1913. Previous history unimportant except that he was weak for several years before admission. For the past three weeks he had complained of a moderate cough, especially in the morning, with tenacious mucus, pain in the throat, dysphagia, and marked aphonia; had lost about 15 pounds in a short time, appetite poor, hardly able to work, dyspnea on exertion. Temperature 98.4°; pulse 88; respirations 20; no night sweats. Physical examination: General appearance, emaciated, glands generally palpable; throat congested. Resonance markedly impaired over both apices and infraclavicular spaces, especially on the right side. Bronchovesicular breathing in these areas. There were crepitant râles over both apices anteriorly above clavicles, and right infraclavicular space. No abnormal signs in rest of chest. Heart sounds distant but no murmurs or hypertrophy detected. Diagnosis: Pulmonary tuberculosis, stage II; patient referred to throat department for diagnosis of the throat condition. There it was pronounced tuberculous laryngitis. Application was at once made for admission to an institution, and in the meantime the patient was treated at the clinic for about a month, during which time he improved somewhat and gained five pounds. On August 21 he was admitted to Bellevue and from there transferred to Seton Hospital, where he remained but a short time, returning home unimproved.

We did not see the patient again for almost a year, as the family resided outside of the district, but on December 14, 1914, he was readmitted to the clinic. The physical signs in the chest were about the same as in July, 1913, but Dr. Seymour, who made the examination, noticed some skin lesions on trunk and scalp. These were large, discrete, with serpiginous borders and pigmented centers. The possibility of lues was considered and a Wassermann, taken the same day, gave a 4 plus reaction. This gave an entirely new aspect to the case. The patient was put on antiluetic treatment and improved gradually until October 6, 1915, when his Wassermann was negative, his voice entirely cleared, and he returned to work, once more becoming a useful member of the community.

The one feature in this case which from the outset seemed to negative the diagnosis of tuberculosis was the absence of tubercle bacilli in the sputum, while in nearly all cases involving the larynx there is a positive sputum; but it should be mentioned that we had only one sputum examination before the man was admitted to hospital. Subsequent sputum examinations were also negative. Apparently no Wassermann was made in either hospital.

Pathologically, there is much similarity between syphilis and tuberculosis; both produce perivascular and peribronchial infiltration, but tuberculosis of the lungs is very common, while syphilis is not, and it was only natural to diagnose the condition, from the physical signs elicited, as tuberculous. The diagnosis of tuberculous laryngitis fortified us in the stand taken. Wassermanns are not done as a routine because many of our patients object to having any blood taken from them.

This case impressed upon us the extent to which the correct diagnosis and proper treatment help to solve a sociological problem as well as the physical, for, thanks to the keenness of the last examiner, a possible tragedy was averted. During the man's inability to work, the family were in great poverty, the patient sullen and morose, quarrelsome, and abusive to his wife and children, even attempting suicide, while now he is able to help along the family income.

CASE IV.—Chart No. 3856. Male. Age 18 years. Admitted to clinic June 21, 1915. Previous history unimportant, except that he had bronchitis frequently as a child. Patient was well until about five weeks before admission, when he began to cough, worse at night, with a slight yellowish expectoration. Pain in the right chest, dyspnea on exertion, no hemoptysis or night sweats. Temperature 100°, pulse 112, respirations 22. Physical signs: Entire left side dull, becoming flat at the base posteriorly, and absent breath sounds. Skodaic resonance at apex, with bronchial voice and breathing and a few râles; no succusion elicited. On right side resonance impaired at apex, with roughened breathing but no râles. Distant vesicular breathing over rest of right lung. Heart: Markedly displaced to left. Apex beat in fourth space in the axillary line. Right border of heart 3 inches to left of midsternum, while left border of heart was about 8½ inches to left of midsternum. This case was diagnosed as chronic pulmonary tuberculosis, stage III. Sputum negative. Wassermann negative. The patient seemed to improve under treatment and gained weight, but there was much discussion as to the diagnosis made. At one time an examiner thought he elicited succusion in the left chest very distinctly and the diagnosis of hydro-pneumothorax was considered. An *x*-ray, taken at this time, showed no tuberculosis on the right side, lung shadow fairly normal, but the left side showed almost no lung or heart shadow at all. There was only a very small area of lung shadow near the apex, the rest of the left side being a blank. *X*-ray diagnosis "possible hydro thorax."

At one of the clinical meetings of the Gouverneur O. P. D. this patient was presented as a case of hydropneumothorax, with the apparent agreement of the physicians assembled. He was again presented as a case of chronic pulmonary tuberculosis before a private medical society, where seven out of eight physicians present agreed in said diagnosis, while one thought it possible but not proved. About this time Dr. Mannheimer was asked to see the patient in consultation and advised that he be admitted to his ward at Sea View Hospital, where an intensive study could be made of the case, temperature and pulse carefully recorded, the sputum morphologically studied, etc. The patient remained for some time at Sea View and was again examined by Dr. Mannheimer at the Gouverneur clinic on May 4, 1916, with the following findings: Thyroid cartilage displaced to left. Marked chest retraction of left side, with dull percussion note, showing consolidation of left lung with pleural thick-

ening. Several bronchiectatic cavities ascertained on auscultation. Compensatory emphysema of right side, with rough and granular breathing at the apex. Probable diagnosis: Chronic interstitial pneumonia with bronchiectasis; one of those cases classed as lung suppurations but not tuberculous. An *x*-ray taken March 17, 1916, corresponded with above findings, and the diagnosis was accepted as final.

CASE V.—Chart No. 4457. Female. Age 42 years. Admitted to clinic April 2, 1917. Previous history generally negative. Patient was well until four months before admission, when she began to complain of cough, following gagging and choking on a bone; moderate amount of expectoration, occasionally blood-tinged; she felt weak and tired easily, occasional fever and night sweats for past three weeks. The chief complaint on admission was cough. Temperature 99.4°, pulse 88, respirations 22. Height 5 feet 1½ inches. Weight 150¼ pounds. Chest examination: Lungs—Left apex impaired, right upper lobe dull, anteriorly and posteriorly. Distinct vesicular breathing on left side and emphysematous on right with rhonchi all over. Bronchovesicular breathing on right side anteriorly. Heart: No apparent hypertrophy and no murmurs; accentuation of second pulmonic. Sputum, 24-hour specimen was negative. *X*-ray showed hilum glands calcified. Extensive adhesions at right base, but not tuberculous.

The diagnosis made at our clinic was chronic (fetid) bronchitis with bronchiectasis, inasmuch as her sputum, at times, had an offensive fetid odor. She was kept under observation for some time, during which she gained considerably in weight, but with no relief of any of the other symptoms. This patient, prior to admission to our clinic and also subsequently, made the rounds of many dispensaries, private physicians, and consultants, in search of a cure for her ailment. On one occasion, the patient states, she was advised to have a thoracotomy done for the purpose of washing a pulmonic abscess, which was the diagnosis of that particular consultant, a course from which we strongly dissuaded her. In June she decided to go to the mountains and to stay there all summer, in the hope of obtaining relief. She remained at Liberty, N. Y., until September, when she returned to the clinic for an examination. At that time the signs in the chest were intensified; she was discharged as a case of chronic bronchitis with bronchiectasis, and not properly belonging to our clinic.

The patient continued throughout the following year to suffer with pain in the chest, frequently coughed up large amounts of fetid sputum, and occasionally had severe hemorrhages from the lungs. About August, 1918, in one of her fits of coughing, she coughed up a large bone (1½ inches long) which nearly choked her; immediately thereafter she felt relieved. Since then all symptoms have disappeared and she feels like "a new born person." The remarkable feature of this case is that none of the *x*-rays taken showed the presence of the bone in her chest.

Each of the cases here presented represents a type which can be confused with chronic pulmonary tuberculosis. There are many points of similarity in the history, physical signs and course between these chronic nontuberculous chest diseases and chronic pulmonary tuberculosis. We know no royal road to diagnosis. Our experience leads us to believe that a careful weighing of all the elements presented, plus time, often a great deal of the latter, is necessary in order to arrive at the correct diagnosis.

291 HENRY STREET.

Hereditary Syphilis and the New Treatment.—Hochsinger of Vienna has been able to show a falling off in congenital syphilis since the introduction of the modern intensive treatment. Before the war the percentage of syphilitic live-born children in a large maternity was around 2½ and now the percentage has dropped to one. This is explained by intensive treatment, which begins in the chancre period.—*Le Bulletin Médical.*

IN WHAT WAY DO FOCAL INFECTIONS CAUSE SYSTEMIC DISEASE?

BY THOMAS J. RYAN, D.D.S.,

NEW YORK.

THROUGH the brilliant work of Billings, Rosenow, and other observers, we have been led to accept as true the basic principles as to the etiological relation between infection and suppuration in the oral cavity and degeneration of vital organs.

There is a general tendency to agree that niduses of infection from various foci, by the distribution of their toxic material throughout the system, may produce secondary foci of infection, which, in turn, are directly responsible for the development of parenchymatous nephritis, diabetes, and sundry other degenerative disorders of vital organs and structures.

It seems to me that—while not denying the ultimate fact that focal infections may and do stand *in loco parentis* to these degenerative changes in glandular and other structures—yet, from the standpoint of strict pathology, we have accorded micro-organisms, *per se*, a somewhat larger share of credit (or perhaps it is blame) for these deviations than they rightfully deserve.

In this connection I feel strongly that the profession has not yet sufficiently considered the exhaustive and scholarly conclusions of Dr. William H. Porter, Professor Emeritus of Pathology and Clinical Medicine of the New York Post-Graduate Medical School and Hospital—recognized as one of the greatest living authorities on these subjects—who holds opinions on these matters which seem to me to shed new light on the causative relation of these conditions.

These conditions define accurately, to my mind, the nature of the process, particularly with reference to the generally accepted claims that focal infections are primarily responsible, or even secondarily responsible, through the development of new foci of infection, for nephritis, diabetes, and other organic deviations.

Susceptibility and Resistance.—Dr. Porter takes the broad position that an individual, to be constitutionally affected by any pyogenic or septic process, must first have developed a susceptibility to infection, through a lowered state of resistance. The virility and the number of defensive phagocytes must first be reduced. And even then the introduction of pyogenic bacteria from an infected gum-structure or a diseased tooth does not suffice to produce bacterial suppuration.

If bacteria find their way into the blood stream of an individual with normal bactericidal resistance, no infection results, because the bacteria are destroyed by the defensive agents within the circulating blood. In order to develop suppuration and degeneration of the tissues the bacteria must be able to locate and propagate in some given structure. If infection occurs in this way, its development depends upon two conditions—the virulence of the germ, and the chemical state of the tissues. In some individuals the vital resistance of the tissues may be so reduced by local injury, or by some nutritional defect, as to fur-

nish favorable chemical or physical soil upon which bacteria may grow, thereby rendering the course of the suppurative process especially unfavorable and dangerous. If the bacteria which gain admission to the blood stream fail to find a favorable nutrient medium, they cannot multiply and exert their pathogenic action. In other words, there will be no *reaction* to their presence.

Again, every group of microorganisms may have innumerable family divisions, so to speak. Some of these groups are highly virulent, some mildly so, and some apparently almost inert. If the inert family were put into a highly resisting and thoroughly nourished individual, there probably would be no deleterious results. Whereas, if the highly virulent type were introduced into a person of low vital resistance, an intense infection probably would be produced. It is a well-known fact, too, that different tissues have different degrees of resistance.

As a result of all these different factors, we get almost innumerable varieties of clinical pictures, so that it is often difficult properly to class the condition.

Focal Infections, Nutritional Disturbances and Degenerative Changes.—This brings us to the crux of Professor Porter's argument. While the ultimate effect of the germ action may be the development of Bright's disease, or diabetes, or arthritis, or degenerative changes in the blood vessels, these results must necessarily follow, first, a lowered resisting state of the organism; and next, in the case of kidney, pancreatic or blood-vessel degeneration, a disordered state of nutrition. This, according to Prof. Porter, is due chiefly to taking into the system an excessive amount of protein substance—more than the system can utilize. If more protein is absorbed than the system has use for, the blood becomes surcharged with proteins. This means that the epithelial cells of the kidneys must take up these substances from the blood stream and eliminate them in some isomeric or transitional form, or else that they must be oxidized into some form in which they can safely be eliminated from the system. If the oxygenating capacity of the system be exceeded, toxic matter will be developed from these proteins, which will have a profoundly irritating effect upon the kidney cells, and ultimately cause degeneration of the kidney structures, if the causative factor, excess of protein in the diet, is not corrected.

The second most frequent cause for degenerative changes in the kidney cells and other structures results from putrefactive fermentation, so frequent in the alimentary canal. This fermentation of the foodstuffs causes the formation of toxic substances in the intestine. The absorption of these into the system, and the attempt to eliminate them through the kidney cells, produces irritation which, if continued over a sufficient period of time, tends to produce degenerative changes in the renal cells.

The third cause of degeneration of the kidney structures results from the presence of microorganisms, acting either directly or indirectly. Directly, as Prof. Porter clearly states, "when they are acting within the system upon the protein structures, which go to make up the integral parts of the body; indirectly, when they are acting upon the protein elements contained in the food products, while in the alimentary canal."

Dr. Porter concludes that:

> In either instance the microorganisms may produce toxic products, oxidation reduction products, or isomeric protein elements. In the one instance they are produced within the system, in the other within the alimentary canal, to be absorbed therefrom in the circulation.
>
> In either case the nutrition in general is impaired, and the kidneys are called upon to perform an excessive amount and an abnormal kind of work—hence their degeneration. It is further highly probable, if not absolutely proved in all instances, that different kinds of bacteria produce different kinds of toxic substances, either of the oxidation reduction type, or of the isomeric protein form.
>
> From all the evidence at our command, it is probable that, in the vast majority of cases the bacterial action, when it acts as an exciting factor in producing renal lesions (kidney disease), is brought about in the alimentary canal, and not within the system. It is the bacteria acting upon the protein elements of the food stuff in the alimentary canal that excite putrefactive changes, and thus indirectly, and not directly, the bacteria act as causative factors.
>
> Insisting, as many of our focal infection enthusiasts do, that bacteria are in all cases the direct and only etiological factor in producing organic lesions, seems like carrying the bacterial side a little too far.

Fundamentally a Disturbance in Nutrition.—So, while it is undeniable that absorption of toxic products from focal infection may produce degenerative changes in certain organs and structures of the body, it would seem quite clear that they do not produce these changes of themselves, by direct action on these organs or structures—as is claimed by most of the advocates of the modern theory of focal infection—but rather by reason of the effect they have upon digestion and nutrition, and particularly upon the transformation of the protein constituents of our food. Therefore, while the absorption of pus germs from infected mouth conditions may cause septicemia or pyemia, the germs do not generally, of themselves, cause Bright's disease, or other disorganizing changes in the organic structures. And, while any or all of these conditions ascribed to focal infection causes may and do result from focal abscesses, they occur because of the disturbances in nutrition, and because of the toxic substances developed as a result of these metabolic disorders. This may seem rather a fine line of distinction, but to my mind it is a most important one, as it shows, reasoning in the most accurate way, on broad lines of pathology, that the conditions produced by focal infection are even more far-reaching than is generally believed; that the problem concerns the physician equally with the dentist; and that both physician and dentist should work hand in hand in the effort to overcome the grave results of these degenerative conditions.

Success in the management of these conditions is not alone a matter of removing sources of infection, but also of correcting abnormalities in the diet, and of recommending general hygienic precautions to be followed out by the individual.

In any event, if everybody in the world could realize the importance of this big question of focal infection, and would take steps to correct the evil, one of the principal causes of misery,

suffering, and early death, would be avoided. And, thanks to the efforts of dentists, medical men, and scientific investigators, this now seems likely to be accomplished.

SOME OBSERVATIONS ON SUBPERITONEAL ENUCLEATION OF THE UTERUS;

WITH A REPORT OF FIVE CASES.

By HOWARD CRUTCHER, M.D.,

JOLIET, ILL.

On January 13, 1904, at the Wesley Hospital in Chicago, assisted by Dr. Hugh Hover, I enucleated the uterus from a Mrs. F., aged 50, for incurable procidentia accompanied with visual indications of early cancer of the lower lip of the uterine cervix. During the progress of the operation the peritoneum was not opened at any point, and in reply to some inquiry concerning the character of the operation I said, in perfect good faith, "This is what is known as the Langenbeck operation, first performed about the year 1820." The patient made a rapid recovery and was alive and well when last heard from several years after her operation. I am sorry to say that the patient objected so strongly to a microscopic examination of the specimen that laboratory confirmation of the diagnosis was not obtained.

My second subperitoneal enucleation operation was performed in New Mexico on December 18, 1907, in the case of an unmarried woman of middle age for intractable uterine neuralgia, the patient being up for a Christmas dinner a week later. The final results of this operation were extremely gratifying.

The third operation was likewise performed in New Mexico during the month of May, 1911, upon a married woman of middle age with a mingled history of active tuberculosis and suspected uterine carcinoma. The results, immediate and remote, were wholly gratifying.

During the month of November, 1919, I performed the same operation twice, once on the 4th at the Chicago Union Hospital, upon a woman of 63 for total prolapsus, causing the most pitiable disablement, and a second time at the Goshen Hospital, in Indiana, on the 27th, for suspected cancer of the cervix. In the former case I was assisted by Drs. Kenneth Scatliff of Chicago and William McRoberts of Joliet. At Goshen I was assisted by Drs. Kreider, Becknell, and Yoder, all of the Goshen profession. Both of these patients made prompt recoveries, thus leaving my five cases of subperitoneal enucleation unmarred by a single death or even a serious complication.

Until within the past few days I have always supposed that these subperitoneal enucleations were merely repetitions of Langenbeck's renowned feat of 1813, but even a casual survey of Langenbeck's original paper ("Description of a Successful Extirpation of the Uterus, Carried out by the Author," *Neue Bibliothek für die Chirurgie und Ophthalmologie*, von Conrad Johann Martin Langenbeck, Vol. I, pp. 551-558, 1817) will show that the author made no claim to having performed a subperitoneal enucleation of the uterus. While Langenbeck does use the words "a true enucleation," in connection with this operation, it is plain that he meant extirpation, for he says that both ovaries were taken away at the same time with the round ligaments. His own words are: "With the removed uterus, and connected with it, were the ovaries and the resected ligamenta rotunda." It is worth noting that this great surgeon purposely left a small section of the fundus "which," he says, "appeared to be still healthy."

Basing my conclusions wholly upon my own narrow experience, the operation of subperitoneal enucleation is far more difficult, bloody, and dangerous than the uncomplicated clamp operation which I have so frequently performed with such admirable results. Making a complete circular incision with a pair of short, heavy, pointed, curved scissors half an inch from the external os uteri, dense fibrous tissue is met with, full of very active blood vessels, which require the application of numerous heavy Kocher forceps. The operator proceeds upwards, adhering closely to the muscular wall of the womb, retracting fully the severed vaginal mucous membrane and instantly securing every bleeding point with dependable forceps, left in position for not less than twenty-four hours. I am unable to say with certainty whether I have in any of these enucleations wounded the uterine artery, but in some instances I have had good reason to think so, always in cases of doubt applying a heavy Kocher clamp, not to be removed for forty-eight hours. It is impossible to make headway save with clean, precise cuts with the scissors, blunt dissection being as dangerous as it is useless. The peritoneal coat, of course, must be not only dense but in some degree elastic, otherwise we could not perfect a true subperitoneal enucleation.

It is difficult if not impossible to identify the precise termination of the mucous canal in the dome of the uterus, and I have in one or two cases had reason to believe that I had left a trifling segment of the mucous tissue in this region, due to the friable character of the structures, but in no case has such a suspicion been confirmed by subsequent developments. When the small clamps, sometimes quite numerous, are removed, it is advisable to apply firm packing in the vaginal canal for some weeks. Some bland silver solution, alternated with balsam of Peru, has given admirable results. I have no case of vaginal obliteration from cicatricial contractions to report thus far. So far as I now recollect, I have never encountered a case in which the normal functions of the vagina have been materially disturbed by the operation of hysterectomy, provided that the conditions demanding the operation were limited to the uterus itself. On the contrary, some extremely happy results have been brought about at times, one bladder totally disabled from complete procidentia being perfectly restored to its normal functions within forty hours.

So far as ultimate results are concerned, the enucleation operation has nothing whatever to commend it over the easier, quicker, and safer clamp method of extirpating the uterus, but when it is indicated it is certain that it is practically the only course left open to us. To attack a large and uncertain mass of fibrous tissues in order to

expose the broad ligaments for clamping or ligating cannot be justified when the uterus may be enucleated by safer methods of dissection. The base of the bladder and the ureters must always be borne in mind, and these can be in no reasonable danger so long as we adhere firmly to the muscular wall of the womb. No operator, whatever may be his skill, is, or ever can be, at home in tissues where pathology has transformed anatomy into a tangled mass of wreckage that defies identification. The one safe landmark is the firm wall of the uterus itself, and most happily we are generally able to identify it with reasonable confidence.

Medicolegal Notes.

Rupture of Aorta from Vomiting an Accidental "Violence to the Physical Structure of the Body."—The Pennsylvania Supreme Court holds that where an employee died in the course of his employment, from a rupture of the aorta, caused by "an extra effort in vomiting," a claimant under the Workmen's Compensation Act was entitled, irrespective of anterior causes, such as a chronic ailment, rendering him more susceptible to such an injury, to compensation, as the rupture itself occurring from such effort would constitute accidental "violence to the physical structure of the body."—Clark v. Lehigh Valley Coal Co. (Pa.), 107 Atl. 858.

Medical Opinion Based on Hearsay Evidence.—A physician, witness for the State in a murder trial, where the body was found in a river, and the evidence was wholly circumstantial, based his opinion that the deceased died from strangulation or chloroform on what he had heard that another doctor had said about the condition of the deceased's brain, and the latter doctor denied such statement. It was held that, as the trial court both verbally at the time and later in writing instructed the jury to disregard such evidence, the error was cured.—Porter v. State, Texas Court of Criminal Appeals, 215 S. W. 201.

Contaminated Water Supply.—The New York Court of Appeals holds, reversing 174 App. Div. 904, 159 N. Y. Supp. 1144, that evidence that a city water supply was badly contaminated, that there was an increase in typhoid cases during the period of contamination, medical opinion that the plaintiff's attack of typhoid fever was due to such circumstances, made a jury question whether the plaintiff contracted typhoid through drinking contaminated water instead of through some other possible cause.—Stubbs v. City of Rochester (N. Y.), 124 N. E. 137.

Expert Evidence as to Existence of Typhoid Fever.—In actions by passengers on a steamship, where the question was whether they contracted typhoid fever from drinking polluted water furnished by the vessel, the court said that "the rules of evidence in cases of this nature do not require scientific certainty; and we think the testimony of the attending physicians establishes, by a fair preponderance of the evidence, the existence of typhoid or similar fevers. The record does not convince us that able and successful physicians, familiar with typhoid fever, are very likely to mistakenly diagnose and successfully treat other diseases as typhoid or paratyphoid. It is true that, in the case of each of several of the libellants, expert medical witnesses of high standing have expressed the opinion that, upon the hypotheses contained in the question submitted to them, the patient was not suffering from typhoid fever, but this, at most, raised only a question of fact; and in several of the cases the accepted hypotheses either did not accord with the weight of the evidence or contained elements either disputed or non-existent."—Chicago, D. & G. B. T. Co. v. Moore, C. C. A., 259 Fed. 490.

Parents' Refusal of Operation—Repetition of Visits—General and Special Employment of Physician.—In an action for malpractice against two physicians by the father of a girl of eight years who had been suffering from osteomyelitis in the radius, it appeared that one defendant, F., a physician of Sherburn, Minn., treated the case for three weeks from November 12 to December 3, when the disease grew worse. The other defendant, P., a former family physician, who practised in another city, Jackson, was called on November 18, attended with Dr. F., examined the arm, and gave directions as to treatment. He did not have full charge of the case, was apparently not expected to return when called, and when he left, gave directions that if they "needed him any more to call him." On the 22nd Dr. P. was again called and attended. Dr. F. was present. Dr. P. gave some directions as to treatment, but did not come again and apparently was not expected to come without being called. Dr. F. continued to treat the arm. It continued to grow worse and on December 2 Dr. P. was again sent for. He was not at home and his son, also a physician, came instead. On December 3 he took the child to a hospital in Jackson, where he and Dr. P. performed an operation next day. Dr. P.'s employment then ceased. In January the parents took the child to a hospital in St. Paul, where another surgeon performed an operation in presence of the defendant, Dr. P., and found it necessary to remove the radius, and this was done.

It was conceded by all that the proper treatment for osteomyelitis is by operation, consisting of opening the shaft of the bone and affording drainage of the pus and removal of diseased tissue. The plaintiff's charge was that the defendants did not advise or suggest this treatment, that if this had been resorted to promptly the arm would have been saved, but that the defendants did not correctly diagnose the case until the disease had progressed so far that the bone was beyond treatment and the use of the arm virtually lost. The defendants contended that they did promptly diagnose the disease and advised the parents of its true nature, and seasonably advised operative relief, and that the parents objected to any operation, until it was too late to save the arm. On this question the evidence was in conflict. The court instructed the jury that if the defendants within a reasonable time made a correct diagnosis and clearly advised the parents of the nature of the ailment, and the importance of an immediate surgical operation, and of the result likely to follow a refusal, and that the parents refused to permit such an operation, their verdict should be for the defendants; that if they failed to diagnose and treat the child with reasonable and ordinary skill and such failure resulted in the injury complained of, then, the defendants were liable for damages. It was held that, under the evidence, this instruction was proper. The question whether the plaintiff had proven that a better result would have followed an operation was held to be in the case, and the evidence was such as to sustain a verdict for the defendants.

It was not considered very material whether Dr. P. acted in a general capacity or as a consultant with Dr. F. There was no question but that Dr. F.'s employment was general. Since the jury found in his favor they could not have found otherwise as to Dr. P., whether his employment was general or as a consultant. It could not in any case be said that the obligation or liability of Dr. P. was greater than that of Dr. F.

The difference between general and special employment relates mainly to the obligation of the physician to continue his attention. If called generally he must give such continued attention and attendance as the condition of the patient requires. But if called specially and only for the occasion, he owes no duty to repeat his visits or continue his treatment. The effect of the testimony of the plaintiff's witnesses was that it was not expected that the defendant P. would return, except when called, and that he owed no duty to do so, and the court properly instructed the jury that he could only be held liable for such damages as resulted from his connection with the case on the occasion of his visits of November 18 and 22. There was no evidence of malpractice at either of the operations later performed, at which Dr. P. was present, nor was there anything in the case to indicate that he was employed to supervise or direct Dr. F. in his absence, and the court properly instructed the jury that he was not liable for what Dr. F. did or omitted to do in his absence. Judgment for defendants was affirmed.—Nelson v. Farrish, Minn. Supreme Court, 173 N. W. 715.

THE PATHOLOGY OF INFLUENZAL PNEUMONIA.

THE pathology of the condition now generally termed influenzal pneumonia is interesting from many points of view. It is a matter of history that this form of pneumonia was very prevalent in army camps on this and on the other side of the Atlantic during the war and, of course, unique opportunities were offered for studying the disease from various aspects. Needless to say these opportunities were seized upon by medical men in Europe, in this country, and in Canada, and a mass of literature on the subject is available which should serve to elucidate in many respects this baffling and obscure malady. In the *American Journal of the Medical Sciences* for March, 1920, Dr. Harry Bakwin has a paper on the gross pathology of influenzal pneumonia in France. Among many details of the general pathology to which he draws attention are the skin manifestations. Of these he found that jaundice was the most common. Changes in the recti muscles occurred quite frequently. At times merely an unusual pallor, dryness, and opacity were present. Such muscles seemed to have lost their elasticity, were brittle and very easily fragmented and torn. As for the respiratory system, by far the most usual lesion encountered in the lungs was acute lobular pneumonia and the next most frequent lesion met with in the same locality was lobar pneumonia. This differed from the lobar pneumonia met with in civil life in its bacteriology, streptococci being found in the lungs nearly as frequently as pneumococci, and in its not infrequent combination with lobular pneumonia. Interstitial pneumonia was another type encountered and these cases differed in their bacteriology from those described by MacCallum. Cloudy swelling of the kidneys was found in almost every case. It was usually well marked. Renal congestion was also frequent. The glomeruli, aside from congestion, were normal. The gastrointestinal tract showed few changes.

The following is a summary of postmortem examinations of 106 cases of influenzal pneumonia that died at a base hospital in France: (1) During January and February, 1919, an epidemic of severe lobular pneumonia occurred about the region of Commercy, accompanied by jaundice, cloudy swelling of the parenchymatous organs and heart muscle, and hemorrhages into the pericardium, renal, pelvic and other viscera. (2) Changes in the rectus muscle were observed in 33 per cent. of the cases. (3) Empyema was rare, occurring in less than 4 per cent. of the cases. (4) Acute laryngitis was comparatively rare, occurring in but 6 out of 38 larynges examined, or 16 per cent. (5) Sphenoidal sinusitis was a very common complication and was found in 20 out of 22 cases examined, or in 90 per cent. (6) Seven out of 35 premortem blood cultures showed pneumococci. The rest were sterile with the exception of one which showed meningococcus. (7) The bacteria found in the organs at autopsy were varied, the *Streptococcus hemolyticus*, pneumococcus, staphylococcus, non-hemolytic streptococcus, *Bacillus influenzæ*, and Gram-negative cocci being found in the various cases in the above order of frequency.

It appears then, from the experience of practically all investigators that the main differential feature of this so-called influenzal form of the ordinary lobar pneumonia is the presence of a large number of hemolytic streptococci, the streptococci in general nearly reaching the number of pneumococci, and those of the hemolytic type predominating. It is instructive to note that Bakwin and his co-investigators seldom found the *Bacillus influenzæ*, thus seeming to be somewhat at variance with the experience of Dr. Herbert French, who in a lecture at Guy's Hospital on January 30, 1920, a summary of which was given in the London Letter of the MEDICAL RECORD, on March 6 last, states his belief that Pfeiffer's bacillus is the cause of influenza. However, it is likely that in cases of death from septic pneumonia of the influenzal type Pfeiffer's bacillus would be swamped by the numerous other germs present and especially by the deadly streptococci. In any event, investigations such as those of Bakwin, MacCallum, French and others are of the greatest value in clearing up moot points of that most puzzling of all diseases, influenza.

EXPERIMENTAL PELLAGRA.

SINCE the time of its recognition as a disease there have been two opinions held as to the nature of the causation of pellagra. At the outset the majority believed that it was due to some peculiarity in the diet of those afflicted, while a few investigators have adhered strongly to the theory that the disease is the result of an infection, and some have gone to the extreme of identifying the insect thought to be responsible for carrying the infectious agent. But during the past few years the evidence in favor of pellagra being due to errors in the diet has gradually been strengthened until it has been shown that the disease could be produced at will by subjecting individuals to certain restricted food intake.

The details of this investigation are now available, for Goldberger and Wheeler have published (*Archiv. Int. Med.*, 1920, xxv, 451) an account of the experiment which they carried on in 1915. Twelve volunteers at a prison camp were kept for a period of six months upon a diet consisting of white wheat flour, corn meal, hominy grits, corn starch, white rice, granulated cane sugar, cane syrup, sweet potatoes, pork fat, collards, turnips, turnip greens, and coffee. This diet is characterized by containing only about one-half of the amount of protein found in the diet of those who were used as controls in the experiment and practically none of this was obtained from animal sources. The diet of the controls was also probably more satisfactory in its mineral composition and richer in both the fat soluble and antineuritic vitamine.

The experiment was amply controlled. All the rest of the population living in the camp were taken as control individuals. The volunteers were rigidly protected from communication with the outside and especial attention was paid to their sanitary surroundings. They were required to do less work and were allowed more rest than the controls. The camp was situated in a district in which pellagra was known to exist and the season of the year was chosen in which the incidence of the disease is lowest. Eleven of the volunteers went through the entire period, and of these six developed symptoms which were recognized as being indicative of the presence of pellagra. All of the volunteers lost weight and strength and developed symptoms that might be considered to have been early symptoms of the disease, but in six the diagnosis was definitely made by several consultants. The skin lesion in these six consisted in a well-marked, bilaterally symmetrical, sharply marginated, and more or less scaly dermatitis on the ventral or ventrocaudal surface of the scrotum. This location of the initial lesion is an unusual one and the authors believe that the location of the initial lesion may be dependent upon the specific quality of the diet, for it has been noted that where several members of one family develop pellagra they are apt to exhibit similar initial lesions, while in different localities and in the same locality in different years the initial lesion is apt to show marked differences in distribution.

In the discussion of the nature of the fault in their experimental diet the authors point out that it was deficient in protein, especially animal protein, antineuritic vitamine, and mineral constituents. On the basis of other experiments they hold the opinion that a deficiency in the antineuritic vitamine is not the essential fault. The case as to the mineral constituents is less clear. There is a certain amount of evidence both for and against the importance of these substances in the production of pellagra. The importance of the protein may be perhaps ascribed to the nature of the amino acids composing it. The publication must be taken as a preliminary report and much further study will be needed to determine the exact substances at fault. It is unfortunate that it was not possible to follow these individuals after their return to a more adequate diet to see how rapidly they returned to a normal condition. The information gained by this and similar studies should render it possible to adopt measures which will result in a marked diminution in the incidence of pellagra in this country. The problem is not wholly solved of course, but much progress has been made toward a solution and the complete elucidation of the mystery is but a matter of time.

THE CLINICAL VALUE OF GASTRIC CHEMISM.

THE work of digestion effected by the stomach is very small; this viscus does not peptonize and renders only a very small part of albuminoid substances effectively assimilable. Its part in the physicochemical phenomena of digestion appears to be especially to dissolve and disintegrate the nitrogenous matter, the intestine completing this preparatory work, submitting the gastric chyme to a more complete elaboration. From this it follows that the motor function of the stomach surpasses its secretory function. If the motor function languishes the stomach becomes the seat of abnormal fermentation, the products of which poison the organism. To react against these fermentative processes the organism has the resource of an antiseptic hydrochloric hypersecretion, a resource not without its danger because it exposes to the possibility of ulcer. If there is a secretory insufficiency the duodenal digestion suffices largely to take the place of gastric digestion, on the condition that the motor power of the stomach is intact.

All things considered, abstraction may be made of the work of peptonization realized by the stomach and to regard this organ as a reservoir of alimentary material, so that two essential conditions dominate its physiology, viz., a regular evacuation and a sufficient content of the gastric fluids in antifermentescible hydrochloric acid. If these data are taken into consideration it will be seen how illusory it will be to estimate the efficiency of digestion by dosage of the gastric peptones; illusory likewise, and for the same motive, the many classifications of dyspeptic states which have been made. Let it also be noted that the normal hydrochloro-peptic secretion does not correspond to an invariable type as some observers have maintained: Schüle and Verhaegen have met with distinct hyperchlorhydria in young subjects who had never experienced the slightest discomfort; on the other hand, Rémond and Mathieu have seen a most characteristic apepsia coinciding with complete health. In these circumstances, if one were guided solely by gastric chemism, it would be difficult to determine where the normal state ended and the pathological began.

It is enough to say that the study of gastric

chemism has only a very restricted importance as regards the general progress of the nutrition. It is impossible to ascertain if a subject digests well or badly by simply analyzing the gastric chyme; the indications furnished by the person's general state, or even by the mere dosage of the excreted urea in twenty-four hours, are otherwise precise in this respect. In the research for secretory anomalies the value of gastric chemism cannot be denied; it offers an excellent basis upon which to build the diagnosis of dyspeptic states, such as hyperchlorhydria, Reichmann's disease, simple ulcer, or carcinoma, but still it is to be recalled that the chemical disturbances of the stomach are not pathognomonic of any affection of this organ. Thus, achlorhydria is not characteristic of cancer, as has been maintained, because it is also encountered in amyloid degeneration, in the serious types of chronic gastric catarrh, and in nervous dyspepsia. The same remark applies to hyperchlorhydria, which is met with in Reichmann's disease, simple ulcer, and gastritis. In all these processes, the diagnostician must not be content with a single diagnostic element obtained by the passage of the stomach-tube. Finally, the individual variations of hydrochloric secretion show the absolute necessity of repeated and minute examinations and their interpretation requires all the sagacity with which the clinician is endowed. So far as the choice of a test meal is concerned, it would seem very rational to avoid Ewald's meal, as it does not exercise much if any stimulation on the hydrochloro-peptic secretion, while that of Germain Sée might be adopted to advantage, as it is chiefly composed of albuminoid substances, and Verhaegen's researches fully confirm this view.

Neurotropic Treponemata.

Chauffard, writing in the *Journal de médecine et de chirurgie pratiques,* February 25, 1920, xci, 4, refers to the continuous changes in our conceptions of nervous syphilis. While tertiary syphilis in general is getting milder as a folk scourge, so-called "XV century cases" becoming constantly less and less common, syphilis of the nerve centers, once unknown, is becoming increasingly common. Improvement in tertiary syphilis of the skin, bones, etc., is due to improved knowledge and perhaps also to slowly acquired racial immunity. That the disease as a whole is milder may be doubted in virtue of the Wassermann disclosures that it is the cause of severe cardiovascular and nervous lesions which destroy life in great numbers, although it seems quite certain that patients properly treated are not much exposed to these dreaded sequelæ. Nervous lesions may be grouped under three heads. First, early meningeal cases revealed by lumbar puncture; second, cases of myelitis which tend to appear with some of the lesions of visceral syphilis, as hepatitis and nephritis; and third, cases of paralysis of the insane and tabes. The latter are usually the sequel of benign untreated syphilis. These patients exhibit a proverbial infrequency of ordinary tertiary lesions, just as races of people who still suffer grievously from ordinary tertiary lesions, as some of the indigenous North Africans, do not suffer from tabes and general paralysis. Again, we know that cases occur in which several men infected from a single syphilitic woman have all later developed paresis or tabes (Nonne, Erb, Morell-Lavalée, *et al.*). Experiments by Levaditi and Marie have shown the likelihood of two strains of spirochete, general and nervous. The latter, it appears, are not originally neurotropic, but develop neurotropism in the organism of the victim. Associated with neurotropism is rebelliousness to the action of ordinary spirocheticides. It has been claimed that paretics and tabetics cannot be inoculated with fresh syphilitic virus, which shows that the antibodies generated by neurotropic strains are very persistent. Data which appear to show a distinct neurotropic strain are doubtless accumulating.

Grippe in Warsaw.

A letter from a Polish physician published in *La Presse Médicale* for April 28, xxviii, 26, states that the type of influenza now prevalent in Warsaw varies extremely. It may be nothing more than a coryza or pharyngitis, or it may take the form of a laryngitis so intense as to require tracheotomy. Bronchitis and bronchiolitis are common, and the highest type of severity is a bronchopneumonia. Unlike the accepted types of influenza attributed to Pfeiffer's bacillus or a filtrable virus, this visitation seems associated almost wholly with the *Micrococcus catarrhalis,* or at least with an organism closely resembling it. This is ordinarily a buccal saprophyte but possesses a resemblance to the gonococcus, meningococcus, and pneumococcus—that is, its variability is such that it may simulate now one, now another, of these three organisms, this variability serving to separate it from the typical *Micrococcus catarrhalis* in its saprophytic form. The author, however, clearly regards this germ as no more than a secondary cause, the essential virus being unknown. Primary pneumonia has seldom been seen. The subject with severe bronchopneumonia gives the impression of a deeply toxic case comparable with toxic peritonitis, in distinction to a septic or infectious case. In most cases the disease runs its course in a few days, bronchopneumonia occurring chiefly in the walking patient. Once a certain degree of severity is attained, medication is of no avail. No reference is made to a peculiarly deadly form of influenza which was reported as prevalent in Poland late in 1919, the gravity of which was attributed to the underfeeding and hardships of the people. Despite the alarming state of malnutrition said to prevail at present, the grippe of to-day is apparently both mild and localized in individual areas.

Role of Intoxication in the Genesis of Psychoses.

Barbé of the Bicêtre briefly outlines the evidence for a toxic origin of psychoses in *La Médecine* for February, 1920, i, 5. One naturally begins with the effects of exogenous toxins. It is hardly just to cite drug addiction as evidence, and the author passes over chronic alcoholism, morphinomania, and

heroinomania, but insists that carbon monoxide can cause true psychotic symptoms beginning with a phase of loquacity with laughter, staggering, genital excitation, and hallucination, and terminating in a period of confusion which may pass off or persist. The mental state may be due to a secondary toxic encephalomyelitis. Of other drugs, lead salts, iodoform and salicylic acid may provoke disturbances of orientation, delirium, etc. In all of these intoxications there may be meningeal alterations as shown by lumbar puncture. Other evidence thus far is experimental as when the leech which sucks the blood of the paralytic dement at the moment of a convulsive access develops neurotoxic phenomena. In animal experiment certain drugs have been shown to pass from the blood through the meninges when the latter have first been damaged by direct irritation. In anaphylactic poisoning the cortex, bulb, and medulla suffer and it is believed that in certain recurrent psychoses there is an anaphylactic component.

News of the Week.

Chiropractor Bill Vetoed.—Governor Smith has vetoed the bill which proposed to license chiropractors in New York State and which was passed by the Senate. In recognition of this action, the Medical Society of the County of New York, at its meeting on May 23, passed resolutions expressing their thanks and commending his action. They also passed resolutions of thanks to the President, Secretary, and Council of the Society for appearing before the Governor and influencing him to exercise his power of veto. This bill provided in effect that the power of licensing should rest in the hands of the State Chiropractors' Society, inasmuch as no one was to be licensed who had not belonged to the society for a year and who was not recommended by the board of examiners appointed by the society.

Infant Recovers Damages for Prenatal Injury.—Supreme Court Justice Ford recently upheld the complaint in a damage suit on behalf of an infant, which was brought on the ground of injuries suffered by the mother shortly before the child was born. The mother fell into an open coal hole in the sidewalk, and the child born seven days later showed the effects of the injury. The mother of the infant sued to recover $10,000 from the owner of the property. This decision has set a precedent. Justice Ford in his opinion said: "It is the boast that the common law is elastic enough to fit itself into new conditions and to progress with civilization and our ever-growing humanitarianism, and it is but a manifestation of this spirit of the law to recognize the responsibility of the defendant to this child."

Milk and Child Health Exposition.—During the week of May 17 to 22 an exposition was held, at the Grand Central Palace, New York City, in connection with the New York Milk and Child Health Campaign. The object of the campaign and the exposition was to further propaganda for improvement in the health and well-being of the children of the city, and to stimulate an increased consumption of milk as a vital and indispensable food for growing children.

Monthly Vital Statistics Review.—The New York State Department of Health has issued the third number of its new publication, the *Monthly Vital Statistics Review*, publication of which was inaugurated with the March issue. The *Review*, intended primarily for the use of public health workers in New York State, is an attempt at a much more elaborate presentation of current official vital statistics than has heretofore been tried in this country.

Vaccination Condemned. — At a recent dinner held in the city of the "Mother Church," the "Medical Liberty League, Inc.," under the presidency of Dr. F. M. Padelford, a homeopathic physician of Fall River, Mass., and composed of "medical, clerical and lay authorities," participated in an acute exacerbation of the chronic anti-vaccination malady with which a certain portion of the population seems to be affected. According to the press reports of the affair, the usual terms, "medical trust," "secret methods," "arch enemies of medical freedom," "persecution of the people," "medical ignorance and arrogance," etc., embellished the program.

Junior Physiologist Needed.—The United States Civil Service Commission has announced an open competitive examination for junior physiologist, to be held July 6. A vacancy at Edgewood Arsenal, Edgewood, Md., at $2,000 a year and quarters for a single employee, and vacancies in positions requiring similar qualifications, at this or higher or lower salaries, will be filled from this examination. Applicants should apply for Form 1312, to the Civil Service Commission, Washington, D. C., or to the secretary of the local Civil Service Board.

Sanatorium for Tuberculous Soldiers.—Surgeon General Hugh S. Cumming, of the U. S. Public Health Service, has announced that the tuberculosis sanatorium heretofore operated by the Medical Department of the Army at Fort Bayard, New Mexico, has been transferred to the United States Public Health Service, and will soon be available for the treatment of discharged, disabled soldiers. This institution provides one thousand additional beds for the care of tuberculous patients.

"Country Doctor" Becoming Extinct Species?—According to both medical and lay press reports, the lure of the city has struck the doctor as well as the farm hand. The farmers, it seems, are finding it difficult to provide medical service for themselves and families while this hegira of the medical men grows apace.

Drug Smuggling Ring Broken.—Revenue inspectors of the Port of New York think they have broken up a ring of narcotic drug smugglers by the arrest, recently, of a former detective as he landed from an Italian steamer. In a false bottom of his trunk were found 840 packages of cocaine. According to customs officials, this country during the past year has been supplied almost exclusively with narcotics for the illicit trade from Italian ports.

Smallpox in Jersey.—Dr. J. C. Price, State Director of Health, has recently urged the need of general vaccination in consequence of the prevalence of smallpox in various places in New Jersey. During the past six months the disease has appeared in fifteen municipalities.

Prison Deaths Attributed to Drug Poisoning.—Two deaths from alcoholic poisoning in the prison hospital on Hart's Island have been charged to apparent lack of supervision of the institution. The prisoners, it is said, had had access to the drug room of the hospital. The results of an investigation into the matter have been presented to Mayor Hylan by President La Guardia of the Board of Aldermen of New York.

Spurious Liquor Prescriptions.—Captain Hubert Howard, Federal Prohibition Director for Illinois, has announced that no fewer than 300,000 spurious prescriptions for liquor have been written by Chicago physicians since the dry law went into effect last January. During that period the number of prescriptions for whiskey written by the three thousand physicians of the Windy City totals 500,000. "Insomnia," "costalgia," "gastritis," "gastrodynia," "cephalalgia," are some of the ailments for which spiritus frumenti was ordered, "one oz. three times daily," more or less. The list of maladies calling for this treatment ranges from "cramps" and "boils" to "diabetes" and "dysentery," with "general debility" playing a leading rôle.

Hospitals for War Veterans.—The House Buildings Committee has authorized, in a bill reported unanimously on June 3, the construction of five hospitals costing $10,000,000, to be used by veterans of the war. The hospitals are to be located, one in the region of the Central Atlantic Coast States, one on the Great Lakes, one in the North Pacific Coast States, one in the Rocky Mountain States and one in Southern California.

Misappropriation of Supplies.—Several high Italian officials have been arrested on the charge of misappropriating materials for war sufferers which had been entrusted to them for distribution.

Dr. William J. Robinson of this city was arrested on June 3 after the grand jury had returned two indictments charging him with criminal libel. He was said by one newspaper to be editor of the MEDICAL RECORD—which he is not.

Bubonic Plague at Vera Cruz.—Several cases of bubonic plague have been reported at Vera Cruz, as a consequence of which all traffic by rail or steamship between that city and the City of Mexico, with the exception of that over the railway to Jalapa, has been ordered suspended by the Health Department of the capital city.

Medical Strike in Madrid.—Press dispatches report that physicians in the Spanish capital who serve the mutual sick benefit society connected with labor headquarters have struck for higher salaries. This leaves thousands of workers without medical attendance.

Medical Society Elections.— The CONNECTICUT STATE MEDICAL SOCIETY at its one hundred and twenty-eighth annual meeting held at New Haven in May elected the following officers: *President*, Dr. George Blumer, New Haven; *Vice-Presidents*, Dr. W. H. Judson, Danielson, and Dr. W. H. Donaldson, Fairfield; *Secretary*, Dr. Charles W. Comfort, New Haven.

The MANCHESTER (N. H.) MEDICAL ASSOCIATION at its annual meeting held in May elected the following officers for the next year: *President*, Dr. George V. Fiske; *Vice-President*, Dr. J. F. Robinson; *Secretary-Treasurer*, Dr. Robert Flanders.

Obituary Notes.—Dr. OTTO E. FORSTER of St. Louis, Mo., died of cardiac disease at the Barnes Hospital on May 17, at the age of 61 years, following an illness of two months. He was graduated from Washington University Medical School, St. Louis, in 1881, specializing in otology, rhinology, and laryngology.

Dr. CHARLES CARSON MESSER, who had practised at Turners Falls, Mass., for thirty-one years, died May 20, at the age of 66 years. He was graduated from Dartmouth Medical School in 1880.

Dr. W. ST. GEORGE ELLIOTT, formerly of London and New York, a graduate of the New York University Medical College, in 1863, died at his home in Pasadena, Cal., on May 23, aged 82 years.

Dr. L. H. MAYER, SR. of Johnstown, Pa., died May 22, at the age of 58 years. He was graduated from Jefferson Medical College, Philadelphia, in 1887, specializing in pediatrics.

Dr. HENRY WEIL of New York City and Harmon-on-Hudson died at his home in the latter place on May 30. He was graduated from the Medico-Chirurgical College, Philadelphia, in 1897, specializing in gynecology.

Dr. RICHARD W. MULLER of New York City died June 3, at the age of 69 years. He was graduated from New York University Medical College in 1879, and specialized in dermatology.

Correspondence.

MINERAL SALTS FOR DISORDERED HEART ACTION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The medical profession in this country—and throughout the world—no doubt will be keenly interested in the recent report from London, to the effect that experimental investigations give promise of discovering a remedy for the relief and cure of heart disease in "certain mineral salts." The announcement was made in the House of Commons, by Captain Walter E. Elliot, M. P., referred to as "the member for science," in the course of a speech in opposition to an antivivisection measure known as the "Dogs' Protection Bill," and judging from the numerous references to the subject in current medical literature and newspapers the outcome, whether a success or failure, is likely to be more or less sensational.

In order that the profession may understand the method of procedure and as a matter of scientific record, a summary of the investigations, so far reported, should prove acceptable. Indeed, such a synopsis may present evidence of inestimable value to physiological chemists on this side of the Atlantic, and at the same time bring out some valuable data from experienced clinicians. Here it follows:

Dr. Eliot says that there are two types of heart disorders, namely, valvular ("V. D. H.") and organic ("D. A. H."), and that of all hospital cases, 75 per cent. belong to the latter class. While valvular disease is not regarded as serious, and but slight progress has been made in efforts to relieve or cure, the "D. A. H." cases are "far more complex," but he adds, "we are making very rapid progress in discovering what problems we have to deal with and in forecasting a cure for the abnormal conditions we discover."

Two varieties of "D. A. H." have been success-

fully demonstrated. For example, under normal conditions as regards innervation, the nerve impulse impinges upon the base (top) of the heart, travels downard (towards the apex), causing rhythmical muscular contractions, thus completing the systole. When the nerve impulse is feebly transmitted or obstructed, normal, rhythmical muscular contractions are impeded, there is irregular or impaired muscular coordination—"every muscle-fiber begins twitching independently, and in some cases one single current, so to speak, goes coursing around the heart." This condition is now known as "auricular fibrillation"—graphically exhibited in the electrocardiograms—and differs but slightly from palpitation or "fluttering," in which the nerve impulse, as shown by electrical tests, is merely distributed over or around the base of the heart.

The following extracts will convey briefly the present status of the inquiry:

"The first stage was the discovery of fibrillation. . . . The second stage of our work, on which we are now engaged, is to discover exactly what fibrillation is, and exactly what is going on in the heart which displays it. . . . The question of cure or alleviation of disordered action of the heart constitutes the third stage of our work, and that has been hardly entered upon."

Abstract analysis of the morbid complexus will at least shed some light upon the cause or causes which interfere with normal cardiac innervation. The inquiry has to deal with chemistry and electricity on the one hand, and both are directly, but independently connected with physiology and pathology. There is, in addition, the psychic factor.

Omitting any reference to the teleological aspect, or biological principles, let us begin with the chemical activities. Thus, chemistry is responsible for the molecular changes in the cells, the oxidation, which is attended with heat. Next in order we must consider the electric phenomena, the force, energy, or what-not which is responsible for the transmission of nerve impulses, which create or produce muscular contractions—mechanical stimulus and more heat.

This it should be observed covers the known range of normal nerve stimuli, electric, thermic, mechanical and chemical. The psychic factor should not be overlooked, but no mention is made of the supposititious theories relating to the intracellular function of oxygen as ozone to account for osmotic pressure, or that the electric discharge is similar to, if not identical with, that produced by radium emanations. It should be added, however, that nerve impulses, as now understood, are transmitted through contiguous nerve units instead of continuous structures—each unit being anatomically independent, and this, of course, gives us a line on the propagation of electrical stimuli, and confirms the belief that electricity as well as chemistry is a factor in creating and maintaining molecular action. Attention should also be directed to a well-known property of the electric "current"—the greater the resistance, the greater the heat produced; also, that heat lessens resistance. These data will be found of value in the analysis of auricular fibrillation. Let us suppose, for example, that some chemical deviation in the cardiac musculature or nerve mechanism hinders, arrests, or destroys the capacity for the transmission of nerve impulses—through the medium of the normal channels. Then we shall have increased heat incident to the resistance, more active tissue change, and a diffusion of the electric current which accounts for the muscular twitching. When sufficient obstruction (resistance) occurs, a short-circuit causes the heart to intermit, with a reflex upon the cerebral centers—and in the case of degenerative changes incident to malnutrition, heart failure is inevitable. The cardiograph shows the effect, but it gives no inkling as to the underlying cause or causes—and it is doubtful if experimental investigations upon animals will solve the occult problem, because we are dealing with a pathological condition which cannot be reproduced in the laboratory. Apparently nerve conduction through the intercellular structures is unimpaired; the difficulty, then, lies in the intracellular chemical deviation, and most likely is due to under-nutrition, mineral deficiency, poisons, focal or other infections involving the protein molecule.

Such being the case, what is the outlook? What measures can be adopted which will enable us to determine the character and extent of the disability? Well, we can employ the galvanometer, as elaborated by Arthur E. Baines (Electro-Physiology, 1918). We know approximately the deflection of the needle under normal conditions. The hand-to-hand galnanometric deflection of a healthy man has been shown to be 350 mm. during the daytime and about one-half, or 175 mm., at night. In the case of lobar pneumonia, deflection of the needle will be probably three times as great on the affected side as compared with the corresponding normal area. Hand-to-hand deflections in asthenia are not only low and constant, but negative, although they gradually approach normal as convalescence ensues. On the other hand, neurasthenia presents a typical illustration of demoralization in nerve conduction—due to chemical deviation in the intracellular substance (?). There is a low hand-to-hand deflection, variable as to sign and frequency—5 to 90 mm.; it is inconstant and fluctuating, distinguishing it from all other nervous affections. I have ventured to characterize the pathology of this disorder as disseminated magnesium infiltration.

The treatment of neuritis, so called, furnishes an apt illustration of the correctness of these deductions. Rarely is it a simple inflammatory reaction, even following trauma, and may be promptly relieved by what is now termed ionic medication—and the same is true in respect to neuralgia and sciatica—where the needle deflection is sub-normal. Most important of all, however, is the fact that it applies in the case of organic heart disease, as the reader can learn, from a casual review of my paper entitled, "Applied Calcium Therapy" (MEDICAL RECORD, February 14, 1920), which includes quite a number of illustrative case reports.

JOHN AULDE, M. D.

1024 WALNUT STREET,
PHILADELPHIA, PA.

Anosmia and Epilepsy. — Alikhan states that anosmia is a frequent symptom of epilepsy and that it may be hereditary and familial in several generations. He gives an account of a family of 30 members, of which 11 were anosmic, 4 hyposmic, and 2 epileptic. After paroxysms of epilepsy it may be impossible to recognize even so powerful an odor as musk. Cacosmia or the subjective perception of disagreeable odors has also been seen in epileptics.—*Schweizerische medizinische Wochenschrift.*

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, May 14, 1920.

Post-Graduate Arrangements in London.—London is progressing in its arrangements to make of that great city a unique post-graduate medical center. When I say London, I mean that the Fellowship of Medicine has now organized and coordinated medical education in London upon the lines suggested at its foundation meeting. The Weekly Bulletin of the Fellowship, which is the organ of the central bureau of that body, provides information with regard to post-graduate facilities in Great Britain, and the consequence of the various efforts put forth has resulted in the Fellowship becoming a recognized center, from which inquiries are answered and information supplied to medical men in all parts of the world. Not only are letters received but medical visitors from Europe and from all the civilized world who are beginning to arrive in numbers, now regard the headquarters of the Fellowship, 1 Wimpole Street, W., as a source whence they may obtain information and where they may find a *pied à terre* amid congenial society. American medical visitors are especially welcomed at the home of the Royal Society of Medicine and the Fellowship as they thoroughly established a reputation as keen and earnest students and pleasant companions in the persons of those who were in London during the war. In the past London has suffered a good deal from the tradition of its inhospitality to the stranger within its gates. While this may have been partly true, the Englishman is naturally reserved, the fault is being corrected. In fact, the American medical men who have been over in recent years have little cause to complain of lack of hospitality. The truth is that those who dwelt among us for a time have learned to know the Englishman better and to recognize that although disguised by a somewhat icy demeanor, his hospitable instincts were only in abeyance and that really when thawed and warmed he is quite a sociable sort of person. As said before the Weekly Bulletin, which is excellently got up, is a printed proof that the possibilities of medical post-graduate work in London as now coordinated are not excelled and are equalled by but one or two medical centers of the world. And it must be remembered that until the war the dearth of post-graduate facilities in the biggest city of the world were so obvious that foreigners, as a rule, gave it a wide berth. It is curious, however, that there seems to be an apathy among British medical men with regard to the post-graduate opportunities in London. The medical men at home fail to realize or are indifferent to advantages in this respect, which are being seized upon with enthusiasm by medical men from abroad. American medical men who come to London are strongly advised to pay a visit to the Fellowship of Medicine.

The Mackenzie Davidson Memorial Fund.—Sir James Mackenzie Davidson was one of the most prominent workers in radiology of the world. His name is generally associated with the development and improvement of radiographic technique, and perhaps especially with that of stereoscopic radiography, and with measurement and localization of foreign bodies. It is due to these methods perfected by him that many thousands of wounded men have been given relief from much pain and suffering. Of course, his reputation was international, and he was particularly well appreciated in America, where radiology has reached so high a standard. In order to perpetuate his memory it has been proposed to raise funds wherewith to endow a Mackenzie Davidson Chair of Radiology at some university. An appeal to this effect has just been issued in the public press by men distinguished in medicine, politics, and other walks of life for funds to carry out this purpose. In this appeal stress is rightly laid upon the undoubted fact that developments in radiology are of the highest importance in many manufacturing industries as well as in medicine.

The first lecture of the foundation established to perpetuate the memory of the late Sir James Mackenzie Davidson was delivered by Sir Ernest Rutherford, F. R. S., at a meeting of the section of electro-therapeutics of the Royal Society of Medicine held on April 16 last. Sir Ernest Rutherford pointed out that the work done by Davidson was both in the direction of rendering the whole matter of radiology a subject of greater scientific precision and dependability, and in elevating it to a position at which it has arrived as a much requisitioned specialty. He emphasized the point that its followers had now arrived at a parting of the ways; the old haphazard methods, inseparable from a laborious emergence, would no longer suffice if real progress was to be made. Hitherto, there had been no systematic teaching of the subject, but individual workers had surmounted the difficulties and had acquired by much labor a working knowledge of the physical as well as the medical side. He commented with great satisfaction upon the establishment by the University of Cambridge of a diploma in radiology and electrology, for which some thirty students in London had already entered. He was of the opinion that until the scheme was well established it would be best to institute instruction in the subject at two or three convenient centers. Lectures were now being given in London and Cambridge. A goodly part of the lecture was devoted to an exposition of Rutherford's own views concerning certain aspects of the effects of radiation on matters which were somewhat as follows: The effects of *x*-rays in various treatments were similar in many respects to those of the beta and gamma rays of radium, but in some cases radium was preferable on account of its case of concentration on a particular region. The effects of the *x*-rays were probably not due to the rays themselves, but to the power possessed by the radiation to eject from matter electrons at a prodigious speed. Some years ago Mr. C. P. R. Wilson of Cambridge, devised a method by which the trail or track of the ejected electrons could be traced and photographed and the technique of this method was illustrated by the lecturer. He compared it to the tracing of the track of a tornado by the path of destruction it left. He considered that the rays possess the power of chemical dissociation of a fairly close chemical combination like water; and that they

also have the power of association or recombination. The effects seen in water could safely be regarded as occurring in the human body when the rays were applied to it, except that the amplitude would be very much reduced and not every part would be hit by the electrons. The main problem of radiology was to find out the conditions under which the rays passing into tissue would destroy the cells or the foreign organism with the minimum of danger to healthy cells. Possibly the radiation might, in the case of a few organisms of disease, have the power of differentiating between the injurious cell and the healthy; and he thought it ought not to be wholly impossible, by the introduction of certain salts on certain solutions into the patient, to produce chemical reactions which would not occur normally. Some such process seemed a condition of further definite advance in the therapeutic use of the rays.

Death of Sir Henry Burdett.—Sir Henry Burdett passed away on April 29 in his 74th year. He was taken ill last February, as the result of overwork, but for some time hopes were entertained of his ultimate recovery, but the improvement in his condition was not maintained, and he died from heart failure. In the medical world throughout the globe he was known for the work he did for the nurses and hospitals and nearly up to the last he was arguing for the retention of the voluntary system and devising plans for its accomplishment.

He was the son of the Rev. Halford Burdett and was destined for the university and the legal profession, but the untimely death of his father when he was 17 changed his plans and instead of going to college he went to a stool in a bank. Then he became a medical student, passing all but his final examinations. For six years he filled the office of superintendent and secretary at Queen's Hospital, Birmingham, and a similar post at the Seamen's Hospital, from 1874 to 1880, when he was appointed to the important and influential position of secretary to the Share and Loan Department of the Stock Exchange, from which he retired in 1897. But while he did valuable work in the field of finance, it is the results of the application of his trained mind and remarkable ability that bore the best fruits and earned for him the undying gratitude of his fellow countrymen. During the period that he was secretary of the Seamen's Hospital he raised the income of the institution from £7,000 to £13,000 a year. In 1877 he established the Home Hospitals Association for Paying Patients, and three years later he opened the first Home Hospital for the Middle and Upper Classes, having raised £26,000 for that purpose. In the course of a paper read before the Social Science Association in Dublin in 1881, Sir Henry threw out the practical suggestion that an annual conference of representatives of hospitals would be most desirable. He subsequently organized the first hospitals conference, which was held in London in 1883. He also did a great deal of work in the science of hygiene and sanitation, he founded and edited the "Hospital" and established "Science Progress." To the general public, however, he was probably best known as the founder in 1887 of the Royal National Pension Fund for Nurses, which proved an extraordinary success. In the work of the Hospital Sunday Fund he took the deepest interest. He published many works on the activities and organization of hospitals and the various phases of the nurse's life and work, while his "Hospitals and Charities," which is almost as well known in America as in England, is the recognized vade mecum on all matters with which it is concerned. Sir Henry Burdett was an untiring worker, he was full of an intense fire of energy. According to his friend, Mr. T. P. O'Connor, he acted in everything he undertook with the suggestion of a machine that was at once swift, relentless, restless, and a little noisy. Though he always appeared tranquil but vivacious, he seemed to be possessed by a perfect fever for work. A man who regarded life as a race with time; with time always hurrying after and threatening to draw level with and even go beyond the work which, as Mr. O'Connor suggests, in a world where so many people are sluggards, produced now and then a good deal of hostility. The world gets the credit for always loving the lover, it does not always love the worker. Sir Henry Burdett was made a K. C. B. in 1908.

LETTER FROM GENEVA.

(From Our Regular Correspondent.)

GENEVA, May 1, 1920.

Change in the University Faculty.—The important event here has been the resignation of Dr. L. Bard, professor of clinical medicine at the University, who has gone to fill the same chair at the University of Strassbourg. It is probably safe to say that Dr. Maurice Roch, of Geneva, will be his successor, and that he is highly competent to fulfil the duties of this very important professorship. Young, still energetic and an excellent *causeur*, with all requisite scientific attainments, Dr. Roch will have a brilliant future. The spring term of the Faculty promises better than last year. During the war it was natural that a great number of students should be absent and their numbers fell low, but the number to attend the spring term has reached 357, but even this is very much below par.

A Chair of the History of Medicine.—It may be of interest to your readers to know that the University of Geneva is the only one of the five Swiss universities having a chair of the history of medicine, which, with the exception of the Italian schools, where some attention is given to this interesting and important subject, is also much neglected in other countries. There is a chair at Paris and one at Berlin and Leipzig and one at Edinburgh. The courses offered in this branch during the spring term at Geneva are: Medicine and religion; an introduction to the study of the history of medicine, two hours a week; lectures on Galen's writings, one hour a week, and lectures on the history of syphilis, one hour a week. During the winter term there are two courses of lectures on medical history, one a complete course of five hours a week, and the other an elementary course of one hour a week.

Early Treatment of Venereal Disease.—At its

recent session, the Committee of the International Office of Public Hygiene adopted the following resolution after hearing the report of Dr. Carrière, the Swiss delegate, and decided to bring it to the notice of the various governments. The resolution particularly insists upon the efficaciousness of the early treatment of venereal disease as a means of prevention, and in Switzerland the opinion of the medical profession is of this mind. I here transcribe a translation of the above resolution, as it appears to have considerable importance and interest at the present time.

"Since 1914, nothing has occurred in the domain of science which can have much of any bearing in causing any change of our ideas in the matter of antivenereal prophylaxis. But experiments collected since this epoch in some countries, as to the efficaciousness of early treatment of venereal diseases considered from the viewpoint of prevention, engage us to recall to Governments the resolution adopted on this point in May, 1914, by the permanent Committee of the International Office of Public Hygiene and to ask them again with emphasis to adopt all necessary measures to render the treatment of venereal affections accessible to all categories of the population, by suppressing all which, directly or indirectly, is of a nature for preventing or delaying the care to be given to patients during the contagious period of their affection. It is particularly desirable from this viewpoint, that gratuitous treatment should not be limited to certain categories of the population, and that all who desire it should be able to benefit by it. In the same order of ideas, we emit the hope that the offices of industrial or mutual insurance companies will eliminate from their statutes the provision which excludes from the benefit of prestation of these offices persons having contracted a disease through their own fault, a provision which refers especially to venereal cases and which goes directly against the carrying out of prophylaxis of sexual diseases based on their early treatment. It goes without saying that it is much to be wished that venereal disease can be treated from now on from the viewpoint of prophylaxis, as are the ordinary contagious diseases, and that the general principles which govern the prevention of these affections might be applied to venereal cases, namely, obligatory notification (to the department of health) and treatment, penal sanction in cases of contamination transmitted knowingly or not, to others; thereto adding those measures which proceed from the nature of the venereal infection and its social consequences, such as that which would compel persons desirous of contracting marriage to obtain a certificate attesting them to be free from all diseases of this kind. But it does not appear to us, given the ideas still current and prejudices relating to venereal disease, that the time has yet come to interfere with them by laws and rules. Such a procedure would, in most countries, meet such opposition that there would be considerable risk of obtaining results diametrically opposed to those desired. What is particularly necessary for the time being, and we believe that particular attention of governments should be directed to this point, is to educate the public in order to change its mentality and prepare it for more severe measures. This education must be methodically carried out with all the means at our disposal, namely, the creation of propaganda associations, lectures, cinematographic demonstrations, the distribution of explanatory pamphlets, having in view all social spheres, even schools, and employing for each of them the means adapted to their mentality. In this propaganda private initiative and the State should be closely allied and they should mutually sustain one another with all their resources. It is also of import to give a kind of specific education to the medical corps, so that sanitary authorities may have at their disposal a sufficient number of specialists qualified for applying those measures which they may judge as serviceable to use, and that the physicians themselves may be in a state to contribute, by their actions and teachings, to the education of the masses. In this order of ideas it seems to us indispensable to combat medical charlatanism, which is especially flourishing in the domain of venereal disease, by severe punishment, as has been asked by the Central Council of Hygiene of Holland, all those who treat venereal disease without being physicians, and who offer or publicly or clandestinally extol, by writings, pictures, or oral explanation, drugs or objects or methods of treatment for the cure of these affections. The majority of States already possess in their laws governing the practice of medicine and pharmacy, measures which without doubt would permit them to intervene usefully. The application of these divers measures appears to us to constitute a first step in the prevention of venereal disease and can even now produce excellent results. The next step will be that of legislative intervention; but we cannot enter on this ground until the soil shall have been prepared by a continued and systematic propaganda."

2. Fracture of the Posterior Tubercle of the Astragalus vs. Inconstant Os Trigonum.—Frederick W. O'Brien reports a case of pain and tenderness in the ankle following an injury received by coming down hard on the heel at the same time twisting the ankle. The diagnosis was fracture of the posterior tubercle of the left astragalus, though with the possibility that what was thought to be a fracture fragment might be the inconstant os trigonum. The right foot was normal and the *x*-ray showed a well developed posterior tubercle. Some months later the patient had pain in the right foot, but could recall no injury. What appeared to be a fracture of the posterior tubercle of the astragalus on this side was found. A month later the roentgenologist reported ununited fracture of the posterior tubercle of the right astragalus and no evidence of separation of recent fracture fragments of the left foot. The treatment of each ankle was by plaster-paris splints. The writer believes there was a definite fracture of the posterior tubercle in the left foot and a separation of the os trigonum from its cartilaginous attachments in the right. If the os trigonum is a separate entity and not an epiphysis, O'Brien says, then the failure to have demonstrated it on the first exami-

nation in the right foot may have been due to the extent and closeness of its cartilaginous attachments which were later separated by slight injury although the matter of roentgen technique should not be overlooked, for unless the angle of rays is correct there might well be an overlapping of structures which would preclude proper definition. Anatomists who insist very strongly that the os trigonum is not the same thing as the tubercle say it may represent practically the whole of the external posterior process, that it may be truly fused with the astragalus or closely joined by synchondrosis. If the os trigonum is only loosely attached or at other times fused with the astragalus, it follows that it might very well be pulled off by strain on the posterior bundle of the external lateral ligament of the ankle. If fused with the astragalus it could be separated by the same forces as fracture of the posterior tubercle, viz., a fall upon the heel with the foot in plantar flexion. It seems fair to conclude the roentgenologist should make a closer study of this region in the presence of clinical signs.

5. The Frost-Lang Operation.—Howard F. Hansell describes a modified Frost-Lang operation as practised by the eye surgeons at the Jefferson Hospital, Philadelphia. The operation called by this name consists in the insertion of a gold ball after enucleation of the eyeball, the recti muscles being united by a suture which is made to include the conjunctiva. The procedure followed by Hansell and his colleagues differs from that practised by the originators of the operation: first, in the use of silk instead of catgut sutures; second, in fastening the recti muscles to the conjunctiva before enucleating the ball; third, in the manner of closing the opening in which the gold ball has been placed.

2. Experimental Study of the Nasopharyngeal Secretion from Influenza Patients.—Peter K. Olitsky and Frederick L. Gates base this paper on an experimental study made during the two epidemic periods of 1918-19 and the winter of 1920 and (on healthy controls) during the interepidemic period in the autumn of 1919. Their conclusions are that, from the evidence obtained in this study, extending over one and a half years, it would appear that there occurs a specific substance in the nasopharyngeal secretions in cases of epidemic uncomplicated influenza. This substance seems to be present only in the early hours of the disease. It has not been found later than thirty-six hours after the onset, nor in cases of secondary pneumonia, nor in secretions from persons free from the syndrome of influenza either during the epidemic or during nonepidemic periods. With this substance the authors were able to induce a clinical and pathological condition in rabbits, affecting the blood and pulmonary structures mainly, which could be maintained and carried through at least fifteen successive animals. For this reason, and also because of the dilution between passages and the shortening of the incubation period from rabbit to rabbit, they concluded that they were dealing with the actual transmission of a multiplying agent rather than with a passive transferance of any original active substance. This active substance is filtrable, and resists the action of sterile 50 per cent. glycerin for at least nine months.

The manner in which the bacteria of ordinary species, such as the pneumococcus, the Pfeiffer bacillus, *Streptococcus viridans* and others are encountered during the course of the transmission experiments and during the experimental reproduction of the condition described justifies the opinion that these microorganisms are secondary in effect. The essential effects are produced by a substance wholly unrelated to these bacteria. During the course of these experiments cultures from the lung tissue of affected rabbits and filtered nasopharyngeal washings from cases of influenza were seen to contain tiny bodies, almost invisible, which decolorized by Gram's method, and which stained with difficulty with nuclear dyes. This phase of the subject is still under investigation.

2. Pellagra Outbreak in Egypt.—Pellagra among German Prisoners of War.—J. I. Enright, in this article, reports his observations during the pellagra outbreak in Egypt on 65 German prisoners of war. A critical analysis of the diets which these German pellagrins ate before capture and during their period of captivity prior to the onset of the eruption is sufficient, the writer believes, to explode the food deficiency theory as a predisposing factor. These diets were ample in both quality and quantity. While an originally good diet may be vitiated by loss through (1) abnormal expenditure of energy, (2) defective assimiliation consequent on impaired digestive function, (3) absence of some internal secretion which is necessary for protein metabolism, an analysis of the entire situation seemed to indicate that none of these factors were operative. In this series of cases a peculiar parotitis was relatively common. In some cases both parotids became enlarged, and after an interval of about fourteen days subsided, while in some they suppurated and discharged much pus. Some six months previous the writer saw a similar outbreak of parotitis among otherwise healthy Turks. He felt at the time that the condition was in some way related to food deficiency. In view of these and other facts the question arises whether the parotid enlargement was due merely to secondary infection from the mouth, or to some other as yet unknown factor. The question is suggested as to whether the parotid possesses a rôle in protein metabolism, and whether there is any possibility that this gland may possess an internal secretion the function of which is concerned in the economy of protein, just in the same manner as the pancreatic secretion is essential for normal carbohydrate metabolism. The writer thinks it would be of interest to discover what changes would take place if complete extirpation of the parotids were performed. He feels convinced that in this series of cases he has established a clear case against a food "deficiency" as being the only factor involved in the causation of pellagra.

3. Syphilis in Diseases of the Heart and Circulation.—Charles W. Chapman holds that there are reasons

for expecting visceral manifestations of syphilis to appear at an unusually early period in the case of those who have gone through the stress and strain of the late war. Cases of atheroma and tabes occurring thus early have been reported, and he concludes that it is fair to assume that the heart and other internal organs are equally prone to premature degenerative changes. A number of cases are cited which point the lesson that it is not safe to place implicit confidence in the patient's denial of having had syphilis when clinical evidence points the other way; that when a patient with organic disease comes before us and there is no history of the more usual infections, syphilis should be suspected and confirmatory evidence diligently sought for, especially in patients at or after middle life. When the cardiac symptoms are not urgent it is advisable to prescribe a period of rest, together with a short mercurial course, before proceeding to the administration of the more direct cardiac remedies.

4. Civil Lessons of the War for the Treatment of Fractures of the Skull.—C. M. Kennedy emphasizes the following points in the treatment of fractures of the vault—none of them really new—which have been firmly established by experience in the war: (1) The advantages of total excision of scalp wounds before dealing with underlying fractures were so firmly established during the war that this procedure is likely to become a routine instead of an occasional step in operations upon civil compound fractures. (2) Perforated metal tubes have been shown to have a really useful place for draining cerebral abscesses. (3) "Postage stamp" grafts are quite as good as muscle for hemorrhage from wounds of the cranial surface of the sinus, and may be cut and applied easily. (4) Surgeons who have done much head work in the war have abandoned plugging for wounds of the superior longitudinal sinus as uncertain and dangerous. (5) Lumbar puncture is useful in certain complications of fracture of the skull, more particularly in hernia cerebri, headache with a tense wound, and conditions associated with a high cerebrospinal pressure. Local anesthesia can be used successfully even in most severe cases of fractured vault.

6. Etiological Factors in Abortion.—Daniel Dougal presents a study of 100 unselected cases of abortion admitted to the maternity department of St. Mary's Hospital, Manchester, the majority of which belonged to the class of incomplete abortions. He finds that the commonest period for abortion to occur is between the third and fourth months. Abortion is comparatively uncommon in primiparæ, less than one-fifth belonging to this category. Most women who abort have borne previous full-term children, and in a majority of cases more than one. Frequent abortions in the same patient are uncommon, and when they do occur are not necessarily due to syphilis. As regards etiology, accidental or reflex causes are present in 18 per cent. of the cases. General disease of the mother, disease or displacement of her genital organs, and gross abnormalities of the fetus or placenta (other than those due to hemorrhage of infarction) are found in 25 per cent. Syphilis, as represented by a positve Wassermann reaction, accounts for 12 per cent., but its influence as the actual cause of the abortion is probably much less, and nearer 8 per cent. From the remaining 52 per cent. has to be deducted the figures for the self-induced group, which is probably not less than 20 per cent. In the present series 8 per cent. admitted taking lead pills, and a number of these showed clinical evidence of lead poisoning. This leaves over 30 per cent. with no cause assigned. Pathological investigation throws little additional light on the subject, as most of the morbid changes found do not produce the abortion, but occur during the operation or some other time. It would appear that the mother is primarily at fault as the result of some diseased condition, whether it be of an organic nature, or merely an increased irritability of the centers presiding over the expulsive action of the uterus.

Boletin de la Asociacion Medica de Puerto Rico.

March, 1920, xiv, 125.

The Onion as Object of Worship, Condiment, and Drug.—Dr. del Valle Atiles writes on this subject, beginning with the statement of Pliny that in Egypt the onion was invoked and sworn by as a deity. Its congener garlic is better known as a drug and quite recently important papers on the therapeutic value of this substance have appeared. The number of local and general conditions in which it has been exhibited is considerable—we refer only to its employment by well known medical men—and comprises wasp stings, ozena, otorrhea, pertussis, tuberculosis, various gastroenteric affections, etc. Diallyl sulphide, the active principle of both plants, has also been separately studied. In the form of a distillate of garlic this remedy goes back to Sydenham and Cullen. It has a somewhat different range of applicability, being more concentrated, and is employed as a rubefacient and counterirritant and vermifuge. The author quotes from numerous handbooks on materia medica and therapeutics of past decades. The active principal of garlic and onion has been much used as an enema for the oxyurias and in this connection the fact has been recorded that in some cases a general reaction accompanied by fever has resulted. It has properties not unlike those attributed to asafetida and the two have been given in combination. The peasants of Puerto Rico are said to give garlic to their children for lumbricoid worms and also apply it to the abdomen as a revulsive and cause it to be inhaled in pulmonary affections.

La Grèce Médicale.

January, 1920, xxii, 1.

The Earliest Epidemic of Grippe.—Rondopoulo refers to the discordant opinions of medical historians on this point. It has been dated variously in 876 A. D., the end of the twelfth century, and not until the close of the sixteenth century. The author believes that Hippocrates described an outbreak of the malady in his section on epidemics, as it occurred in Perinth, a Thracian village, in the year which corresponds to 426 B. C. There is a notable correspondence here to the description of influenza by Huxham, in England, in 1733. In both there was cough, which was the predominant symptom; angina, pain in the limbs, chills, fever, coryza, laryngitis, bronchitis, and pneumonia, lassitude and progressive myasthenia, which even culminated in paresis. The author therefore calls "epidemic cough" as it appeared at Perinth the first recorded account of influenza. He disagrees with those who see in the plague of Athens as described by Thucydides any form of influenza, for this was clearly some exanthematic fever, the nature of which is quite obscure.

Acute Cervicofacial Cancer Simulating Actinomycosis.—Gensollen refers to cancers which present evidences of inflammation, suppuration and fistulation in the actinomycotic region of the neck and jaw. It is evident that to cancer has been added an infection of buccal origin. The discharge in these cases will contain none of the yellow grains seen in actinomycosis and biopsy if undertaken will show evidences of prickle-cell cancer, but to be on the safe side an intensive course of potassium iodide might be given, for this will also be of diagnostic value should the case turn out to be syphilitic. But since these cancers are usually quite inoperable and since the iodide may notably aggravate the state of the cancer the author warns against the procedure and would depend on the microscope with an injection of salvarsan for diagnostic use.—*Journal de médecine et de chirurgie pratiques.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 19, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

The Prevention and Serum Treatment of Lobar Pneumonia.—Dr. RUSSELL I. CECIL made this presentation, which was illustrated by lantern slides. By way of introduction, he said that pneumonia, including bronchopneumonia, was the most serious acute infectious disease with which we had to deal, the death rate exceeding that from tuberculosis. Lobar pneumonia was more important from the economic standpoint than bronchopneumonia because it usually attacked the young and able, while bronchopneumonia was seen for the most part in infants and the aged. It was much more difficult to institute sanitary measures against the spread of pneumonia than against intestinal disease, because it was necessary to teach people not to sneeze and cough in the faces of their neighbors, and because inevitable overcrowding in cities made it difficult to prevent the conveying of the disease from one person to another. The old theory was that most individuals carried pneumococci in their upper respiratory tract and that with lowered resistance autogenous infection occurred, but more recent studies indicated that the normal mouth rarely harbored a virulent type of pneumococcus except when the individual had been exposed to the disease. Types I, II, and III were rarely found in healthy individuals, except among doctors and nurses who were caring for someone with pneumonia. In treating pneumonia, it was necessary to treat the patient by isolation and sterilization of everything that came into contact with him. Carriers should be treated by some of the disinfecting solutions that had proven of value in the army. The above facts made evident the importance of some method of protection against pneumonia that was more effective than sanitary measures. Prophylactic vaccination was possibly such a method. Lister, in South Africa, where the types of pneumococci were somewhat different from those met with here, had been successful by the use of mixed pneumococcus vaccines in producing immunity against those types of pneumonia in a large group of miners. It was decided to make observations as to the value of prophylactic vaccination against types I, II, and III pneumonia at Camp Upton. About 12,500 men, 40 per cent. of the camp strength, were vaccinated, and 60 per cent. remained unvaccinated. Those vaccinated received three injections of a pneumococcus saline vaccine of types I, II, and III, the first dose being three billion, the second dose six billion, and the third dose nine billion. The plan had been to keep these men under observation for five or six months, but they departed at the end of ten weeks, during which time no case of pneumococcus types I, II, or III pneumonia had developed among the men who had received three inoculations of the vaccine. There were only 17 cases of pneumonia of all types among those receiving the vaccine, while there were 173 cases of pneumonia among the unvaccinated. Among the unvaccinated the mortality was 28 per cent., as against 11 per cent. among the vaccinated. As these figures were encouraging, the Surgeon-General had sent the speaker to Camp Wheeler to make further observations. Here conditions were somewhat different in that lipovaccine was used instead of saline vaccine. There was a much larger percentage of recruits, mostly rural, among the troops, and the coming of the influenza epidemic complicated matters. Their experience with the lipovaccine indicated that it did not possess so great a degree of antigenic action as the saline vaccine. From September 21 to December 20, 1918, there were under observation about 16,000 men. Approximately 80 per cent. were vaccinated against pneumomoccus types I, II, and III pneumonia. Among the vaccinated there occurred 32 cases of pneumonia of the types vaccinated against, while among the unvaccinated there were 42 cases. The mortality among the unvaccinated averaged 22.3 per cent., while that of the vaccinated was 21.7 per cent. It was found that following the use of the lipovaccines antibodies did not develop until a week after vaccination. Revising their figures on this basis, it was found that there were only eight cases of the types of pneumonia vaccinated against. Believing it desirable to confirm these statistics by animal experiment the speaker, in collaboration with Dr. Blake, had conducted experiments on monkeys at the Army Medical School in Washington. The monkey was suited to such investigation as it got pneumonia almost like man—high temperature, leucocytosis, rusty sputum, similar physical signs, and a crisis on the eighth or ninth day. If given large doses of the pneumococcus the monkey always died, and at autopsy the same kind of consolidation of the lung was found in the monkey as in man. They were able to protect monkeys with vaccine made from living cultures of pneumococci, but with the killed cultures, using doses comparable to the doses used in man, they had not been able to get satisfactory immunity. When, however, large doses of killed cultures were administered in three subcutaneous injections none of the monkeys thus protected by vaccination got pneumonia, but the controls did. The experiments giving this result were made on rhesus monkeys, while the previous experiments had been performed on Philippine monkeys, which seemed more susceptible to pneumococcus than the rhesus. Furthermore, small doses of pneumococcus vaccine given intravenously to rhesus monkeys afforded complete protection. These experiments on monkeys gave a rational basis for human pneumococcus vaccination. The reactions following these injections were about the same as those following antityphoid inoculation, but larger doses were required. They had not had much success in vaccinating against Type IV pneumonias and thought it better for the present to concentrate their efforts on the study of Types I, II, and III. As to the indications for vaccination against pneumonia, there was certainly need of it in the army where crowding was necessary, and in recruiting stations men should always be vaccinated against pneumonia. Vaccination was also indicated during epidemics of influenza, in institutions and in outdoor workers, policemen, miners, etc., who were exposed to the weather. It was perhaps also indicated for nurses, doctors, and hospital attendants exposed to pneumonia in the wards of hospitals. Another place where it would be useful was in people who were subject to repeated attacks of pneumonia. Vaccination against pneumonia was contraindicated in those suffering from pulmonary tuberculosis and in acute respiratory infections; in such cases it should be postponed until the acute attack was over. As to the serum treatment of pneumonia, those familiar with the work at the Rockefeller Institute were aware that Type I antipneumococcus serum was effective against Type I pneumonia and that by its use the mortality had been reduced from 30 per cent. to a little over 7 per cent. Type I serum had not come into such wide use as its efficacy would indicate. Dr. Cecil cited experiments on monkeys with Type I pneumonia showing a very definite result upon temperature and bacteremia produced by Type I antipneumococcus serum. Controls treated with normal horse serum showed no such effect on the blood culture or temperature. All of the monkeys treated with Type I serum recovered, though they had been infected with lethal doses of Type I culture. The controls died. Moreover, if serum was given early, the disease was practically aborted. In other monkeys, almost moribund with Type I pneumonia, serum treatment was started late in the disease, and even in these cases persistent treatment resulted in a favorable termination. This meant that every case of lobar pneumonia in man was entitled to a bacteriological examination of the sputum and to serum treatment if he had Type I pneumonia.

Dr. FRANCIS G. BLAKE expressed the opinion that we would all have to agree that the consistent work that Dr. Cecil had carried on in the study of prophylactic vaccination in influenza and pneumonia had added a great deal to the subject in general and offered great hope of supplying us with the means of preventing this most serious disease at least to a cer-

tain extent. What had his evperiments shown as to the duration of immunity offered by Type I pneumococcus? This question was important because if it was necessary to vaccinate at frequent intervals it was a handicap unless vaccination could be made absolutely atoxic. During the course of their work in Washington it appeared that prophylactic vaccination might not prove of great value. The disappointing results were due probably to the great susceptibility of the Philippine monkeys to the pneumococcus vaccine, one one-thousandth of a c.c. killing them. With the killed vaccines administered to the rhesus monkey they were absolutely able to produce immunity. The susceptibility of the rhesus monkey was more comparable to the susceptibility of man, and much less than that of the Philippine monkey. The serum treatment experiments spoke for themselves and were particularly valuable because they furnished the first experimental evidence with adequate control demonstrating the value of serum, though it had been felt that this was so by those who had been using the serum for some years. These experiments brought out three points very definitely: 1. The importance of beginning treatment early and this point could not be too strongly emphasized. The serum treatment should not be regarded as a last minute effort to rescue the patient from the grave, and that was the general rule in any disease treated by serum. 2. There should also be a great deal of enthusiasm in maintaining persistent treatment at least three times a day and not desisting until the patient was well. 3. Even though through unavoidable circumstances treatment could not be begun early it should always be tried in the hope that severe cases might be saved as in the monkeys.

Dr. HENRY T. CHICKERING said that although the results of Dr. Cecil's later experiments might not have been as encouraging as he hoped they would be from the results in the first experiments at Camp Upton, nevertheless he felt that the work ought to be continued, particularly since the later work was complicated by the influenza epidemic. In Lister's work the vaccines were given intravenously and that might account for his striking results. In their study of pneumonia Dochez and others had found that immune bodies lasted only a short time and that agglutinins lasted only for a short period, but these might not be the only index of immunity. They had had one very striking case at the Rockefeller Institute. A boy had had fourteen attacks of pneumonia in seven years and in spite of a rather imperfect course of vaccine treatment he developed pneumonia again in the hospital. Attempts were made to find the types of pneumococci present in the attacks. Several attacks were of Type III and there was a typical Type II, and also Type IV. Everyone who has worked with pneumonia recognizes the value of the intratracheal method of producing experimental pneumonia from the investigator's standpoint. It was important to emphasize what had been said with regard to the early use of the serum in animals; they saw the same thing in their patients. If one was able to type the case within forty-eight hours of the chill and when there were signs of incomplete consolidation, one or two treatments with the serum were often sufficient, whereas later on one must give eight or ten treatments. In the majority of cases it was relatively easy to get the sputum. The time to get it was at the first examination. Percussing the patient and attempts at deep breathing on his part usually started coughing and expectoration and a good specimen of the sputum should be obtained at that time. Another point which was brought out and which should be emphasized was the importance of keeping up the treatment religiously until the patient was surely over the acute course of the disease. Dr. Cole recommended 100 c.c. doses of serum at eight hour intervals; and the results were quite good using twelve hour interval treatments. The treatment should be continued as long as the temperature was 101° or above. Of course one should be on the lookout for complications so that if there was a rise of temperature due to an empyema he would not continue to treat that with serum. There was an impression among some clinicians that the serum localized the disease and that the organisms were agglutinated in the capillaries in various parts of the body and there set up a focus of infection. Judging from a small group of cases it seemed that it not infrequently happened that several cases of empyema occurred following the serum treatment, but that might be explained on this basis: One very rarely had empyema with Type III pneumonia. The Type III pneumonias were of two groups, one group running a mild course and the other group being very severe, so that they did not have a chance to reach the empyema stage before death occurred. The empyemas among Type II pneumonias seemed to be more numerous, but he felt that if they had carefully controlled statistics they would find that there were actually no more empyemas among the Type I infections than among the Type II pneumonias. In working with mice it had been found that there were certain maximum doses above which the serum exerted no further effect. If the infecting dose were more than .3 c.c. of a virulent health culture of pneumococcus Type I it made no difference how much serum was given, the mice usually died. If a case was seen late and one found 75 or 100 colonies, even if the serum was given persistently, not infrequently the patient died, if not of the primary pneumonia of some complication. The cases that had empyema were probably the severe cases that without the serum treatment would not have reached the empyema stage, and that probably explained the fact that empyema seemed to occur oftener in the cases treated with serum.

Dr. CECIL said that regarding the duration of immunity following prophylactic pneumococcus vaccination was a problem which he planned to investigate in the near future. His impression was that pneumococcus immunity lasted several months and that it would be necessary to repeat vaccination every year in order to give protection during the season when pneumonia was prevalent. Lister's work was done on negroes and they seemed to tolerate vaccination better than the white race. There seemed to be no relation between the degree of immunity and the amount of protective substance in the serum of monkeys. In their serum-treated monkeys they had not met with empyema. In respect to influenza, one argument against the influenza bacillus was that it was difficult to obtain this organism by culture. They had found that with monkeys the influenza bacillus in some instances appeared and then suddenly disappeared, and that it spread rapidly from one part of the respiratory tract to another. In some cases it disappeared altogether within twenty-four hours. He thought that in many cases the influenza bacillus initiated the disease and was then supplanted by the pneumococcus or streptococcus. Dr. Cecil cited an instance in which a volunteer took a freshly isolated influenza bacillus culture, receiving the bacteria directly in his nose. In about three hours he began to have a headache and the leucocyte count went down from 11,000 to 8,000. His symptoms were sore throat, slight coryza and general malaise. On the second day very few influenza bacilli were found except in the leucocytes. During the second day he was quite uncomfortable, but by the third day he had recovered. It was a question in this case whether we were dealing with a real infection or simply an intoxication. If he was infected with the Pfeiffer bacillus there was very slight bacteriological evidence of it on the second day.

The Relation of the Influenza Bacillus to Influenza.—Dr. FRANCIS G. BLAKE presented this contribution. He said that from time to time, during the years following the discovery of the Pfeiffer bacillus its etiological relationship to influenza had been questioned because it was shown that *B. influenzæ*, or an organism apparently indistinguishable from it by the tests available were not infrequently present in the mouths of normal individuals, because it was found not infrequently associated with other disease affecting the respiratory tract, such as measles, pulmonary tuberculosis, bronchiectasis, bronchopneumonia, etc., and because of the apparent difficulty of demonstrating that it possessed pathogenicity for laboratory animals, a fact which lead some investigators to the opinion that the influenza bacillus was merely a saprophyte and possessed no pathogenicity for man. It seemed quite

clear, however, that none of these objections could be maintained as valid reasons for abandoning the conception of the possible etiological importance of the Pfeiffer bacillus since it was well recognized that many bacteria whose etiological relationships to various diseases affecting the respiratory tract was fully established might be found in the upper respiratory tract of healthy individuals, and were also found in association with other pathological conditions than those which they commonly caused, as, for instance, the pneumococcus. It was further thoroughly established that B. influenza, at least certain strains of the organism, might be pathogenic for man since it had been found as the only organism present in cases of meningitis, endocarditis, pneumonia and other conditions. That it might be pathogenic for animals had been ably shown by Wollstein and others. Such, in brief, was the status of the influenza bacillus at the outbreak of the present pandemic. With the outbreak of influenza in 1918, the failure of many bacteriologists to find *B. influenzæ* in more than a small proportion of cases greatly shook belief in its etiological relationship to influenza. A careful investigation of such reports, the essayist believed, would show more or less wholesale routine laboratory examination carried out under the stress of war conditions, frequently without the use of adequate media or sufficient attention to the cultural peculiarities of the influenza bacillus. This opinion was supported by the fact that many bacteriologists throughout the world, thoroughly familiar with the technique of cultivating the influenza bacillus had found this organism constantly associated with the disease, both in its early stage before complications had arisen and also present in a large proportion of cases in the bronchi or lungs at autopsy. Although such investigations appeared to have established the constant associatin of Pfeiffer's bacillus with influenza, its mere presence, even in 100 per cent. of the cases, constituted only suggestive evidence and by no means proof of etiological relationship. According to Koch's postulates it was furthermore necessary at least to reproduce the disease experimentally in animals or man by inoculation with pure cultures of the organism and having reproduced the disease to recover the organisms from the experimental disease, and again to produce the disease in other animals. A review of the literature showed that in the majority of animal experiments reported the methods of inoculation had been by subcutaneous, intraperitoneal, or intravenous routes, and it was not to be expected that a disease which might safely be classified as a respiratory infection could readily be reproduced in animals by introduction of the virus by other than the natural mode of infection by man. The fact that attempts to reproduce the disease by inoculation of the mucous membranes of the respiratory tract had failed might be due to failure to take into consideration that such pathogenicity as the influenza bacilli possessed might be rapidly lost upon artificial cultivation outside the animal body. Further experiments to reproduce the disease were undertaken with Dr. Cecil at the Army Medical School in Washington. The detail of these experiments was described and illustrated by means of lantern slides from which the following summary was deduced: 1. Bacillus influenzæ, when attention was paid to maintaining it at a proper grade of virulence. could initiate in healthy animals an infection of the mucous membranes of the upper respiratory tract which might spread by continuity to the lower respiratory tract, producing a tracheobronchitis, and in a certain proportion of cases a characteristic type of bronchopneumonia. Control experiments with highly virulent strains of pneumococcus and hemolytic streptococcus had shown that these organisms did not possess this property and that they must gain admission to the bronchi before they could initiate an infection of the respiratory tract. 2. The disease experimentally produced by inoculation of the nasal and buccal mucous membranes with *B. influenzæ* was essentially identical with influenza in man with respect to its symptoms, clinical course, and complications. 3. *B. influenzæ* could produce in animals a characteristic type of bronchopneumonia which was identical with the kind of pneumonia which had been described as typical influenzal bronchopneumonia of man and which had been ascribed to infection of the lungs with *B. influenzæ*. 4. In short, these experiments showed that *B. influenzæ* could produce the clinical syndrome of influenza. Dr. Blake stated that though this evidence appeared quite conclusive there remained certain definite objections to accepting the Pfeiffer bacillus as the primary cause of influenza, which might be divided into two groups, (1) those based upon general theoretical grounds or upon negative experimental evidence, and (2) those based upon positive experimental evidence. Without going into these in detail, Dr. Blake pointed out that of the general arguments against the influenza bacillus two of those most commonly advanced had been the undoubted presence of influenza bacilli in the throat of normal individuals and in association with other respiratory diseases than influenza. These had been disposed of early in the discussion. However, there were certain other probabilities, one of which was that when we used the term *B. influenzæ* we were in reality applying a single name to a large group of organisms which possessed a certain limited number of common morphological and cultural characteristics. Another and perhaps more important general argument advanced against the influenza bacillus was the brief incubation period of the disease, which suggested that it was communicable only in its earliest stages. These facts, however, did not seem necessarily incompatible with the acceptance of the Pfeiffer bacillus as the cause of influenza. The well-recognized difficulties in establishing infection in animals with the *B. influenzæ* suggested that its power of infectivity might be limited to a brief period of its life cycle. After discussing the positive experimental evidence brought forward by Dr. Williams in Dr. Park's laboratory, namely, that every influenza bacillus was different from nearly every other influenza bacillus and hence the influenza bacillus could not be the cause of the pandemic, Dr. Blake suggested as harmonizing apparently opposing facts the possibility that the pandemic disease was primarily initiated by an as yet undiscovered organism and that there resulted under the influence of this virus a concomitant infection with *B. influenzæ* which was responsible for the principal clinical manifestations of the disease influenza. Only future investigation would determine whether this assumption was correct.

Dr. WILLIAM H. PARK said he thought Dr. Blake was going to speak only of the evidence tending to indicate that the Pfeiffer influenza bacillus was the cause of influenza. He had, however, added some of the evidence on the other side. The Research Laboratory had carried out an interesting accidental experiment. Four of the laboratory assistants at different times had been sprayed with fresh cultures of the influenza bacilli by the needle being pressed off by the pressure of the fluid in the syringes. Two of these persons had developed a moderate infection and in both of these the type of culture which was sprayed into the nostrils was the type obtained during the infection and for many days afterwards. The other two did not develop the infection, though one became a carrier for several weeks. Dr. Blake spoke of the fact that the early fulminating cases might show during the first day the Pfeiffer bacillus in pure or nearly pure culture and later would show mainly the streptococcus, pneumococcus or other organisms. They had not found this always the case. Two fulminating cases coming under his observation at the beginning of the epidemic which died within three days and in both the smears and cultures made from the lungs showed enormous numbers of a hemolytic streptococcus, and there were apparently no other forms of microorganisms in the lungs. Undoubtedly influenza bacilli were present in the trachea. Only a small minority of their acute cases (20 per cent.) at death showed influenza bacilli in the lungs. Dr. Williams and her associates had tried to isolate a filterable virus, but with negative results. The simple finding of a filterable virus in a few cases would of course prove nothing more as to the etiology of influenza than finding an unidentified new pathogenic microbe. It would still be necessary to prove that such a virus was the cause of the pandemic and not one of the complicating infections. One

of the questions that must be considered in etiological investigations was "What are the marks of a case of epidemic influenza?" Until we agreed upon some definite clinical picture or established some causative microbe it would be difficult in any given case to differentiate the ordinary respiratory infections from influenza. We did not really know that the influenza of 1892 was etiologically the same disease as that of 1919 or whether what we considered the typical cases represented chiefly the effects of the unknown virus alone or the combined effects of the Pfeiffer bacillus, the streptococcus, and the pneumococcus with it. Were we certain that the early milder European outbreaks in 1918 were true influenza, and also the cases designated as influenza between the epidemics of 1892 and 1918? Dr. Williams had searched the cultures from 100 cases but did not find the epidemic strain. When investigators had spoken of the significance of finding the Pfeiffer bacillus in 100 per cent. of the cases they used the name in a very liberal way. They really meant they had found many very different types of the organism. These could not possibly be from the same epidemic source. The findings suggested very strongly that these persons were influenza bacillus carriers before they were attacked by the influenza. Earlier investigation had always indicated this. The Pfeiffer bacillus had been found in every case of whooping cough and in 90 per cent. of persons having acute measles and in a large percentage of cases in other respiratory infections. Dr. Williams had taken cultures from separate groups and had isolated ten or twenty colonies from the cultures of each in order not to miss the infecting strain selecting those developing first on the plates, those developing later, and those developing last. She had picked out these colonies from the cultures from undoubted epidemic influenza, but instead of finding an epidemic strain she found a multitude of types. These findings convinced them that the Pfeiffer bacillus had not been established as the cause of influenza. The pathological and bacteriological results of the work of Dr. Blake and Dr. Cecil had in his mind been very important in experimentally demonstrating that lesions could be formed in monkeys by the Pfeiffer bacillus similar to those seen in the pneumonias occurring in influenza.

Dr. HANS ZINSSER said that Dr. Cecil and Dr. Blake had indeed carried out Koch's postulate with the influenza bacillus and had produced lesions similar to those produced by this organism in some human cases, but the question as to whether the condition they had produced was true epidemic influenza or corresponded merely to a secondary condition analogous to the pneumococcus and streptococcus lesions was still open. Dr. Park had clearly stated the problem when he said that the production of lesions in monkeys had little etiological significance in regard to the pandemic under discussion. The conditions which Dr. Cecil and Dr. Blake produced in the monkeys' lungs and the similar conditions often spoken of as influenza at the present time were not those seen in the cases of influenza during its early epidemic stages in France, and as he understood in this country as well. Dr. Zinsser described this condition as it occurred in France, where it was characterized by rapid dissemination, sudden onset, violent headache, muscular pain and fever, but by absence of respiratory or other local symptoms, at least during the early phases of the epidemic. It usually lasted three days; none of these cases died; all got well. The disease was at first spoken of as "three day fever." Later, throat symptoms appeared and in these influenza bacilli were found. The disease at this time was certainly not the type that was seen later in the camps of this country and were being seen in the hosiptals, associated with the pneumococcus or the hemolytic or other streptococci, according to the locally prevailing type. It was his first impression that "pure" uncomplicated influenza was the relatively mild disease described, the pulmonary lesions, pneumonias, etc., representing secondary infections. In studying the flora of the respiratory tract the influenza bacilli were often found most abundant at first in the upper air passages, but were later displaced by secondary invaders. The presence of the influenza bacilli in normal throats had not yet been studied statistically with sufficient thoroughness, and was a problem open to possible error because it was difficult to say who had been exposed to the infection and who had not been. It was quite possible that influenza bacilli would be found in the throats of many people who had not been sick at all because of a fair amount of resistance. If the influenza bacilli were regarded to be the cause of the disease as at first observed, it was difficult to understand why the patient should be so terribly ill with nothing but a small focus of influenza bacilli in the throat, giving rise there often to nothing more than a local pharyngitis; this could be explained only on the basis of a production of a poison by the organisms comparable to exotoxins of other bacteria. Recent work in the Columbia Medical School Laboratory by Mrs. Parker showed that the influenza bacilli produced powerful poisons during the early stages of their growth in liquid media which were toxic for rabbits. Just exactly what these poisons were was not yet clear to them, especially since they were finding poisons quite similar to them in connection with other bacteria, but it was not impossible that these poisons might actualy be formed in the body, and would then easily account for the severe symptoms accompanying the localized infections. The only way to definitely ascertain the nature of these poisons would be by determining whether or not they could produce neutralizing antitoxins. They were at present inclined to believe that they were not identical with the true exotoxins, but their nature was being carefully studied at the present moment. The typing of influenza bacilli and the work done by Anna Williams, Wollstein, and their coworkers in this direction promised considerable light on this subject. Dr. Zinsser said that he had not followed the most recent work of the Department of Health, and did not know whether they were using the complement fixation test or the agglutination test.

Dr. PARK replied that they were using largely agglutination.

Dr. ZINSSER said that in Dr. Longcope's clinic they had begun to examine convalescent patients by complement fixation with influenza bacilli. A great many of these patients seemed to have shown complement fixation with various antigens, but this work was just beginning and there had not yet been an opportunity to make a sufficient number of controls on normal sera, and it would be very difficult to obtain sera from anyone at the present time and be sure that they were normal. However, this direction of research would also have a certain amount of bearing on the problem under discussion. Dr. Zinsser further said that of course it has been long known that the influenza bacillus could cause a variety of respiratory infections in human beings; that the work of Dr. Cecil, and Dr. Blake had certainly made it seem somewhat more likely that the influenza bacillus was responsible for what was commonly spoken of as "flu" or influenza but that it did not bring positive proof of this particular phase of the problem, and that, while he himself was inclined to favor the etiological significance of the influenza bacillus, he thought that final judgment must be withheld until some of the apparently contradictory points of evidence had been more thoroughly cleared up, however much one desired to incriminate the influenza bacillus.

Dr. BLAKE, in closing, said in reference to Dr. Zinsser's question as to the relation of the influenza bacillus to the production of pneumonia, he wished again to emphasize the fact that although they were able to produce pneumonia by the influenza bacillus, the point they stressed particularly was that the influenza bacillus was able to initiate an infection of the upper respiratory tract which appeared the same as the type that appeared in the spring 1918. He saw a great deal of this type of infection at Fort Sam Houston in Texas and thought at the time that it was the same kind of an infection that they were having in the army in France. That suggested a question which he would like to ask Dr. Park, that was, whether it was necessary that an epidemic should be caused by one strain of the organism, and whether it might not be possible that a number of strains were involved, which when conditions were right caused an epidemic. In an epidemic of pneumonia among monkeys at least four

types of the pneumomoccus were concerned. During an epidemic it was doubtful whether the influenza bacillus along was often found associated with pneumonia, though the influenza bacillus alone did produce pneumonia in a small proportion of cases.

The Treatment of Influenza.—Dr. SAMUEL A. BROWN said that our knowledge of the exact cause of influenza was so deficient that it was necessary to approach any plan of therapy with a note of empiricism, but because of this we should not ignore the many facts that had been gleaned from an extensive clinical experience in the handling of the disease. Before considering the treatment of influenza we must consider our problem. The disease, in a large percentage of cases, began apparently with an infection of the mucous membranes of the nose and throat or the respiratory tract followed by symptoms of general infection, associated with all the complications with which we were familiar. Symptoms of toxemia were apparent from the beginning, and as the period of convalescence was approached the toxicity was often more marked and was one of the problems which might often be more serious than the active symptoms of the infection. Many of the milder types of influenza were accompanied by a long period of convalescence extending over weeks or months with evidence of vasomotor, cardiac disturbances, anemias, etc., so that in considering the treatment the toxicity seemed to be the factor in mind from the beginning of the disease to the very end. There were three definite stages, the stage of invasion, the stage of active infection, and the stage of convalescence to consider. The treatment of the disease was not a problem purely for the nose and throat specialist or for the internist alone. Treatment must be directed first toward the destruction of the invading organism locally and generally. There must also be systematic treatment for the control of the active symptoms and minimizing the effects of the toxemia and shortening the period of convalescence. All cases, even though very mild, must be looked upon seriously. From the very beginning of the disease the patient should be instructed to remain at home and in bed at an even temperature as one of the most important factors in the control of the disease. A cathartic should be the first item of treatment. Local treatment of the nasal and respiratory mucous membranes should be begun at once with alkaline irrigations and a solution of argyrol or some preparation of silver either for the destruction of the infective organisms or for both protective and prophylactic reasons. Of the drugs which were of value in the constitutional treatment, the preparations of quinine stood out as fundamentally the nearest to a specific which we had, and while we were entirely unable to prove its destructive power upon the specific bacteria it was given for much the same reason as that advanced for giving large doses in pneumonia. Quinine should be given in two or three grain doses every two or three hours until there was evidence of cinchonism. The dosage should then be reduced but the quinine continued. The drugs for the symptomatic treatment should be combined with the quinine such as phenacetin for the reduction or control of pain, headache, and temperature; small doses of codeine for the control of the cough and throat and salicylic acid also as analgesics. This combination was the usual basis of the grippe capsule so-called and might be modified to meet the symptoms evidenced by the individual case, such as the addition of caffeine citrate in cases in which the depression was very marked, or strychnine in the cases associated with slow pulse and depression. Another plan of treatment which the speaker used extensively consisted in the administration of Dover's powders, three grains to three grains of quinine every three or four hours. This plan was particularly applicable where there was a good deal of dryness of the skin, slight cough and restlessness. From his personal experience this procedure did not seem as advantageous as the plan outlined above. There had been many cases of intensification of depression resulting from the use of aspirin during the epidemic of last year. The third factor of importance was the increasing of elimination. For this purpose large quantities of fluids, preferably the alkaline waters, solution of bicarbonate of soda, Vichy, kalak, or other waters of this type so that the kidney and skin activity could be utilized in the elimination of the toxin, and combined with this high colonic irrigation of three to five gallons at a temperature of 118° to 120° every day or every other day, depending upon the severity of the infection. The irrigating solution should contain one dram of Rochelle salts and one dram of soda to the quart. The depression which was associated with the end of the active stage should be counteracted in the beginning by moderate alcoholic stimulation and forced feeling. These patients as a rule objected to food, but it must be insisted upon and given in small quantities frequently. As the patient passed from the stage of active infection to convalescence the use of alcohol should be increased to the point of liberality, the quinine and phenacetin decreased and the codeine and heroine continued in decreasing doses if the irritable cough persisted. The irrigations should also be continued and owing to toxic changes in the blood mass the administration by hypodermic of strychnine or arsenic on alternate days should be prescribed together with absolute rest and stimulating massage. The treatment of this stage was to the speaker's mind one of the most important ones and a feature in the treatment often neglected. In the more severe forms of influenza infection the quinine might be given hypodermically in the form of quinine and urea hydrochloride 15 grains, or in some other soluble form, three or four times a day. Associated with the administration of the quinine in its various forms Dr. Brown said he had extensively used camphor hypodermically, giving from 20 to 40 grains in twenty-four hours. The use of diaphoretics, such as spirits of Mindererus, white drink, etc., might also be of considerable value in increasing the activity of the kidneys and skin. In latter-day prescribing many had omitted to use some of the old-fashioned preparations which had been useful for generations and which were just as useful to-day if selectively applied.

Dr. HUBERT V. GUILE stated that there was no question that patients who had been put to bed early in the course of their disease and had been kept there five or six days after the temperature became normal had been far less liable to develop relapses and the subsequent likelihood of bronchopneumonia. As for medication his experience had been limited to the use of aspirin, salol, and sodium salicylate, all of which seemed to give the patient relief from bodily discomfort and therefore had a distinct therapeutic value. Expectorants and occasionally sedatives were indicated for the control of associated bronchitis. A large number of drugs had been recommended for the treatment of influenza, but the disease was of such short duration and the outcome so invariably favorable, that it was difficult to say just how much the results were due to treatment and how much to the patient's own immunity. Because of the frequency with which it was complicated by bronchopneumonia one was almost justified in regarding any case of influenza that had persisted more than five days as more than likely to have developed pneumonia. With the exception of the serum treatment of Type I pneumonia, which occurred on only a small minority of cases, we were again compelled to resort to purely symptomatic treatment. At present he feared the great bulk of treatment in pneumonia was directed toward the prevention of circulatory and cardiac failure, when it was by no means certain that this was a frequent cause of death. In addition to the serum treatment of pneumonia there were a few other therapeutic measures that gave promise of ultimate usefulness. Haldane had recently brought to notice the importance of the proper administration of oxygen inhalations in the treatment of anoxemia, which he defined as a condition in which the rate of supply of oxygen to the tissues by the blood in the systemic capillaries was insufficient for the normal processes of life. This he maintained was a common situation in the bronchopneumonias of the so-called influenzal type. He seemed to have placed the use of oxygen on a rather more scientific basis and we were possibly justified in a procedure that was formerly justified as more or less of an extravagance. Another procedure, the outcome of our experience abroad, was the use of intravenous hypertonic glucose

solution. This seemed to be of distinct value in the critically ill presenting marked toxic symptoms. Its beneficial effects were attributed to the restoration of dehydrated tissues, to its slight caloric value, and to its possible tonic effect on the heart muscle. Non-specific protein therapy, which had proved of some value in the chronic infective arthritic diseases had been applied in bronchopneumonia and there seemed to be promise of some assistance along these lines. The same statement held true of passive immunity obtained by the use of serum of convalescent patients. Lumbar puncture was another measure that was occasionally of value in delirious patients. It was always a good practice in ruling out the possibility of meningeal involvement and at the same time had a distinct effect in quieting the delirium. As for the use of drugs in the treatment of pneumonia, digitalis seemed to be fairly generally accepted as the one upon which most reliance could be placed. It should be given early in the course of the disease in sufficient dosage to digitalize the patient slightly. For emergency stimulation the writer had found camphor and caffeine the most efficient, with adrenalin if the blood pressure was unduly low. Pituitrin had been useful in combating tympanites.

AMERICAN ASSOCIATION FOR THORACIC SURGERY.

Second Annual Meeting, Held in Atlantic City, N. J., June 9, 1919.

THE PRESIDENT, DR. WILLY MEYER, OF NEW YORK, IN THE CHAIR.

I. President's Address: The Necessity for the Application of Differential Pressure in Thoracic Operations.—Dr. WILLY MEYER of New York delivered this Address. (See MEDICAL RECORD, October 11, 1919, xcvi, 15.)

II. A Partial Review of the Subject of Military Surgery of the Chest from the Point of View of the Experience of the World War.—1. Report of 160 Penetrating War Wounds of the Thorax.—Dr. GEORGE J. HEUER of Baltimore, Md., based his remarks on 160 cases of penetrating chest wounds which came under his personal observation at an evacuation hospital. The circumstances surrounding the treatment of these cases were most favorable. The hospital was large and in a relatively quiet sector, and therefore the early evacuation of patients was not necessary. Practically all the cases remained under his care for from three weeks to three months; in other words, until the incidence and the results of the treatment of early and late complications were known. With the exception, perhaps, of an occasional late pulmonary abscess which might have occurred unknown to them, they knew the late as well as the immediate results in this entire series; and the mortality, he believed, represented the entire mortality. Certain facts regarding chest wounds had been well established when we entered the war; first, that over 60 per cent of cases which died at evacuation hospitals died within forty-eight hours of hemorrhage, shock, and open "sucking" thorax; and second, that the later deaths were practically entirely due to infectious complications. Surgeons had concerned themselves with the attempt to lower the immediate mortality and to prevent the later infectious complications, and their activities had taken two chief directions: first, to differentiate chest wounds into those which required immediate operation and those which could be safely treated expectantly—in other words, to establish operative indications—and, second, to develop surgical procedures which would lower the immediate mortality and at the same time prevent the infectious complications. The larger problems, then, in the treatment of chest injuries had been recognized and in part solved, and their work had no other merit than that which a careful study of a series of cases might give to unsettled points in the treatment of thoracic injuries. When analyzed from the standpoint of treatment, the cases could be grouped into those requiring immediate operation and those which might be treated expectantly. The operative indications in the former group were: 1. An acute hemorrhage threatening life; 2. Open sucking chest wounds; 3. Large retained foreign bodies; 4. Extensive fractures, chiefly of the ribs. From the standpoint of wounds, the cases presenting these indications included the large shell wounds and the bullet wounds with extensive fractures. Often two or three of the operative indications coexisted in the same case. The latter group, those which might be treated expectantly, included those with closed thorax in association with hemo- or hemopneumothorax, and from the standpoint of wounds included the clean perforating and penetrating bullet wounds unassociated with extensive fractures and the small shell wounds of similar character. The operative treatment of the first group naturally depended on the condition of the patient. Shock was common and often profound, and therefore an ideal operation might not be possible; but, given a patient in fair condition, and presenting one or more of the operative indications above, the ideal operative procedure consisted of the following steps: (1) A long skin incision excising the wound of the soft parts. He had always followed the wound of entrance. (2) Resection of 10 cm. or more of a single rib, resection of all fractured ribs, control of bleeding from the parietal wall. (3) Wide opening of the pleural cavity and careful removal of loose bone fragments from the region of the wound. (4) Complete evacuation of the hemothorax. Removal of foreign bodies if lying freely in the pleural cavity. (5) Inspection of the lung; removal of bone fragments and foreign body from the lung tissues; excision of the wound tract in the lung if possible; resection of the injured lung tissue if necessary; careful suture of the lung with a deep and pleural layer of sutures. (6) Complete closure of the wound without drainage, by muscle plastic if necessary. It might be noted in passing that the through-and-through wounds perforating the entire lung did not yield themselves to the treatment outlined under (4). The treatment of these cases consisted in as careful cleaning of the tract as possible and control of hemorrhage. As regards closure without drainage, he had had an excellent opportunity to note wounds in which the pleura was sutured but the soft parts left open. Over a third of them had become infected, with a resulting pleural infection. As would be noted later, this did not occur if the chest was completely closed. The non-operative treatment of the second group consisted in absolute rest in bed, morphine to induce quiet, measures to combat shock, repeated aspiration for cultural purposes, and repeated larger aspirations beginning on the third day and continuing until the hemothorax was completely evacuated. When cultures showed infection of the hemothorax, rib resection and drainage was immediately done under local anesthesia, Carrel-Dakin treatment of the cavity was instituted, and the wound was closed by secondary suture as soon as the cavity, as proven by cultures and smears, was sterile. Of the 160 cases, ten were admitted in a moribund condition and died within an hour untreated. Forty-five cases presented one or more of the positive operative indications mentioned above and were immediately operated upon. Seventy-five per cent. of them had open sucking wounds and were seriously shocked; yet in a majority a fairly complete operation was done. Twenty-five per cent. of the cases died, chiefly from shock and other serious injuries. Seventy-five per cent. recovered. It was a fact worthy of comment and indicating the adequacy of the complete operation as outlined above that in the cases personally operated upon by him there was not a single instance of pulmonary, pleural, or chest-wall infection following operation. The wounds healed per primum. The lung was completely expanded within a week or ten days. In the entire series no special anesthesia apparatus was employed and there was no respiratory accident. The lung was not distended nor the air in the chest aspirated at the end of the operation. One hundred and fifteen cases, including ten moribund on admission, were considered belonging to the non-operative group. From all causes, and I include cases dying, from other injuries, 18 per cent. of this group died; if we exclude the cases moribund on admission, 8.5 per cent. died. Fifteen per cent. of these 115 cases developed secondary infection in association with hemothorax and were subjected to imme-

diate rib resection and drainage. The cavities in these infected cases were sterilized and the wounds closed before the patients were discharged. The total mortality in this series from all causes was 20 per cent. If the cases moribund on admission and dying untreated were excluded it was 13 per cent.

2. War Wounds of the Chest.—Dr. CHAS. GORDON HEYD of New York read this paper by invitation. All wounds of the chest were potentially infected. Modern surgery, however, was able to obviate, inhibit or prevent infection if the surgeon was able to operate during the golden period of operability—the first eight hours, preferably four—between the receipt of injury representing contamination and the development of infection which ordinarily became apparent about the eighth hour. The ideal operation contemplated (1) debridement of all soft tissue about the orifice of entry or exit, particularly all portions of contused, necrotic or infiltrated tissue in or about the area of the wound; (2) the regularization of all bone ends; (3) complete esquillectomy or the removal of all bone fragments, particularly the indriven spicules of bone in the lung or pleural cavity; (4) the removal of the foreign body, unless smaller than the nail of the little finger; (5) a debridement of the traject in the lungs and, if badly infiltrated or lacerated, resection—partial or complete lobectomy; (6) adequate surgical and anatomical repair of the lung by suture; (7) complete toilette of the pleural cavity, removal of blood, foreign bodies, fragments of bone, portions of clothing, etc., many times lying free within the costophrenic sinus or impinging upon the opposite chest wall; (8) repair of the diaphragm and such intraabdominal exploration as would seem indicated; (9) the hermetical closure of the wound in the chest wall by any of the accepted methods. A satisfactory classification of war wounds of the thorax could be arranged as follows: 1. Perforating wounds, through and through, due to bullet; 2. Perforating wounds, through and through, due to shell fragments; 3. Penetrating wounds, with retention of large foreign body; 4. Penetrating wounds, with retention of small foreign body; 5. Tangenital wounds; 6. Cave-in, stove-in or crushed-in thorax; 7. Sucking wound or open thorax; 8. Combined abdominal or multiple wounds. In his experience there were operatively proved injury to the chest, 51 cases; gunshot wounds, 40, with 15 deaths; bullet, 4, with 1 death; undetermined 7, with 2 deaths. The types of injury were perforating, 23; penetrating, 17; tangenital, 2; cave-in, 2; thoraco-abdominal, 7. Total mortality, 18. Mortality by type of injury: tangenital wounds, 2, with no deaths; perforating wounds, 23, 6 deaths; penetrating wounds, 17, 6 deaths; cave-in, 2, with 1 death; thoraco-abdominal wounds, 7, with 5 deaths; admitted in pronounced shock, 19, with 8 deaths; admitted with sucking wound, 15, with 11 deaths; hemothorax, 28, with 12 deaths; hemopneumothorax, 5, with 2 deaths; the ribs were fractured in 18, with 8 deaths; the scapula 6 times, with 4 deaths. The average duration between injury and arrival at hospital was 19 hours; the earliest time was 4 hours and the longest time was 96 hours. A summary of the surgical indications for operative intervention could be tabulated as follows: 1. The closure of sucking wounds of the chest wall irrespective of the retained foreign body or the mechanism of production of the injury. 1. Continued bleeding or unusual hemorrhage. 3. Grossly infected, contused or contaminated wounds of the soft tissues. This variety eliminated the cases with a clean cut rifle bullet wound or the penetrating type of wound due to small shell fragments. 4. Wounds with fracture of the ribs, clavicle, scapula or vertebra, complicating the original or primary injury. 5. The retention of foreign bodies other than small éclat. By small was meant a shell fragment certainly not larger than the nail of the little finger. 6. The onset of a progressive hemopneumothorax. 7. Stove-in or crushed-in chest with multiple fractures of many ribs whereby the bone ends protrude into the pleural cavity bringing about a laceration of the lungs. In wounds in the scapular region perforating high up between the vertebral column and the scapula it was rather difficult to obtain adequate access to the pleural cavity. Trephining the scapula proved a very unsatisfactory procedure and excision a needless loss of bone substance. It was much better to divide the rhomboid muscles, the serratus magnus and the latissimus dorsi at the lower angle of the scapula and to throw the scapula upwards and outwards. If the nature of the wound would permit resection of the fourth or fifth rib was carried out from the midscapular line upwards to the posterior axillary line. Where an injury was low down with compound comminuted fracture of the sixth, seventh or eighth rib in the midaxillary region, then the incision was enlarged by resecting the seventh rib. Through such an incision the pericardium was sutured twice, and in another case a large transdiaphragmatic hernia was replaced with ease. When the diaphragm was injured well out in the costophrenic sinus the central portion was occasionally sutured to the parietal pleura. This technique was employed only in combined thoracoabdominal cases and where it was essential to close the pleural cavity and at the same time insert gauze into the renal fossa or into the liver. Rarely a loss of substance of the diaphragm could be repaired more easily by suturing the lacerated edge to the parietal pleura than by closure of the defect.

III. Thoracic Surgery in War: 1. Lessons Applicable in Civil Practice.—Dr. SAMUEL ROBINSON of Santa Barbara, Cal., in presenting this paper, said the association might well be grateful for the contributions to thoracic surgery resulting from the late hideous war. It was an ill wind that blew no one good. It behooved us to elicit from the voluminous and often varied experiences conclusions applicable not, it was hoped, to future wars, but to civil practice. The handling of gunshot wounds of the chest, now so greatly improved by the teachings of war, was, alas, one of the least vital problems in times of peace. The bullet wounds of civil life when not immediately fatal, would be treated much as before. The shell fragment inducing the intrathoracic lesions which had presented the gravest problems in the therapy of war, might concern us no more. And although thoracic surgery of war which this association chiefly labored to combat had had little to do with those chronic diseases, other than that of empyema, he rejoiced to note that certain facts established by the war would be applicable in the struggle against these diseases of civil life. Of these war contributions to thoracic surgery the essayist confined himself to the discussion of wide open pneumothorax and of pleural infection. The wide open, socalled blowing wounds of the chest were improperly treated at the early part of the war. The success following the immediate, though temporary, closure of these wounds in 1916, emphasized certain principles in intrathoracic surgery which might well attract attention. Surgeons were at first misled by the old conception that an open pneumothorax was a fortunate occurrence associated with laceration of the lung, resulting in the collapse of the lung and the consequent limitation of hemorrhage. The difference between a closed and an open pneumothorax was evidently not appreciated. A bullet wound of the chest might be accompanied by a certain degree of lung collapse, either from a temporary entrance of air through the wound or from the escape of air from a lacerated lung, or from the compression of a hemothorax. The spontaneous closure of the chest wall opening in such perforating wounds sometimes resulted in a closed pneumothorax which was an ideal condition for the control of lung hemorrhage. The open pneumothorax associated with blowing wounds, however, added certain dangerous features which were not at first recognized. Death resulted in the earlier cases not always from hemorrhage but often from the asphyxia resulting not only from the loss of inflation on the wounded side but also from the restricted work of the lung on the sound side. Eventually it became apparent that a prompt though temporary closure of the gaping shell hole in the thorax not only saved many lives, but relieved the distressing symptoms of hopeless cases. The cyanosis and dyspnea were promptly relieved, the heart action was improved, and the mental anxiety and emotional shock alleviated. The improvement of surgical resistance consequent to the preliminary closure of the wound permitted subsequent operative procedures for the arrest of hemorrhage, for the extraction of projectiles, and for the repair of the lung. In animal experiments we were inclined to regard the phenomena associated with wide

open pneumothorax as due to the mobility of the mediastinum resulting in the movement of this partition toward the uninjured side at that moment when the sound lung required for its inflation that all the walls of its pleural cavity remained fixed. Although the mediastinum in man was more rigid than in animals, the work of the sound lung, nevertheless, was greatly restricted in the presence of a wide-open pneumothorax. Disturbances in the pulmonary circulation following this condition, with overwork of the right heart, were also responsible factors in the fatal outcome of blowing wounds left open. Analogous to this demonstration of the dangers of a wide-open chest associated with blowing wounds were the fatal consequences resulting from wide open drainage of empyema associated with the hemolytic streptococcus pneumonias. The death rate in the early part of this epidemic following the usual empyema drainage technique was appalling. Here again the asphyxiating effect of an operative blowing wound was demonstrated; the septic fluid was generally thin, the lung was often only slightly adherent. The lung of the opposite side was suddenly overworked, and this asphyxiating effect, added to the already toxic state of the individual, generally resulted fatally. Just as it was finally learned that blowing shell wounds should be promptly, though often temporarily closed, it became apparent in the streptococcus empyemas that a wide-open wound should be avoided; that frequent aspirations were necessary preliminaries to drainage; that drainage should not be established until the fluid was thickened and the exudate had become sufficiently plastic to prevent complete collapse of the lung. Even when drainage became necessary suction devices were of greater value than in the routine treatment of empyemas following the pneumococcus pneumonias of civil life. For many years it had been recognized that a sudden wide open drainage of a thin empyema fluid, particularly in children, was a matter of some concern. But here again the war had thrust before us a new problem demonstrating that in certain infectious diseases, as well as in traumatic open lesions, a persistent, wide open pneumothorax might serve as a fatal accompaniment. The dangers of open, postoperative pneumothorax were again recognized in connection with extensive intrathoracic operations for the removal of projectiles from the lung and pleural cavity. If at the end of such operations the pleural cavity was left open for drainage the outcome was obviously endangered, and ere long it became the established custom to close the chest wall tight after operations upon the lung, although it was obvious that infection had been carried into the chest and must be taken care of either by general resistance or by subsequent aspirations or drainage. It had soon become apparent that if septic fluid accumulated following intrathoracic operations for shell wounds it could be removed subsequently, but that if drainage were established at the time, the intrathoracic negative pressure would be destroyed, lung reexpansion would be limited, and the excursion of the sound lung would be deleteriously hampered. These three examples in the treatment of war wounds and streptococcus pneumonias of the disastrous effect of wide open pneumothorax had made a profound impression upon our minds, and it behooved us to profit by these teachings in our future intrathoracic work of all sorts. It had occurred to him that we might be persuaded by these particular war teachings regarding open wounds that in our attack upon intrathoracic pathology of civil life we might more often perform several stage operations, knowing that in the interval between them if the chest were closed tight we would not thereby increase the risk of death from sepsis, but that we would on the contrary stimulate both lung and heart action, which thoracic operations were so prone to derange. The war had impressed upon us the importance of avoiding persisting open pneumothorax. Inasmuch as drainage of the pleural cavity provided a postoperative pneumothorax, the problem was presented in the earlier part of the war as to whether drainage was necessary for the purpose of removing infection despite the dangers of pneumothorax associated with it. In other words, the old problem was reawakened as to whether open pneumothorax or the retention of infection was the greater menace to life. Although the surgery of war had added further proof that the peritoneum had extraordinary resistance to infection, it had also persuaded us that the resistance of the pleura to infection was greater than had been generally supposed. Frequent aspirations of infected material had resulted in recovery without eventual open drainage. It was obvious that when the greater portion of the infected pleural contents had been removed the pleura was often capable of resisting the infection which might remain. It had been demonstrated, furthermore, that the pleural cavity, unlike the abdominal cavity, might be mechanically cleansed previous to its closure after an intrathoracic operation. Some operators had employed simple swabbing out of the pleura with absorbent material; others had washed out the cavity with various antiseptic solutions before closing it. At the present time it was not possible to conclude that any one antiseptic had been of greater specific value in cleansing the pleura than another. Furthermore, the evidence was not yet conclusive that the antiseptic treatment of the pleura after operation had removed infection any more successfully than the mere mechanical cleansing. One might even argue that inasmuch as postoperative aspirations of the pleura had generally been necessary regardless of the handling of the pleura before closure, that the pleura might have withstood the infection in conjunction with aspiration even if no means had been employed to cleanse it before closure. It was conceivable that following civil operations for excision of portions of the lung for abscess and bronchiectasis, it might be advisable to swab out the opened pleural cavity both mechanically and antiseptically, even though the remaining lung might continue to feed infection to the pleura. Surely the tendency would be increased to close the chest after such operations and to rely upon subsequent aspirations of infectious fluid. A cleansing then previous to such closures might become a definite asset to our technique. Medical publications were now including extensive reports of the employment of Carrel-Dakin solution in empyema, and not a few conscientious surgeons were convinced that the convalescence in such cases had been greatly enhanced by the use of such methods of lavage. It was to be expected now that although pleural lavage had gradually become practically obsolete in the treatment of empyema prior to this war, many doctors would now employ antiseptic solutions for the irrigation of postpneumonic empyema cavities; the more enthusiastic would regard this treatment as essential. The problem of pleural lavage in civil practice would now be reawakened, but should it not be our inclination to continue to regard lavage as of problematical value? That a large number of cases of hemolytic streptococcus empyemas had appeared to convalesce more rapidly because of lavage could not be denied; nevertheless, great fears might be entertained that the practitioners would undertake to employ this lavage treatment in the commoner types of pneumococcus and streptococcus empyemas, regarding it as a cure-all in these cases. Surgical clinics would receive cases of chronic empyema with inadequate or ill-placed drainage which had been subjected for months and years to antiseptic irrigation, in which the attending physician had failed to recognize that any irrigation or any paste failed to close the cavity of any considerable size unless the mechanical conditions of drainage were adequate. With the added enthusiasm for lavage, men would fail to recognize that plastic operations were necessary in the presence of a thickened pleura and retracted lung and that such could not be cured by irrigation. Although the nature and extent of the discharge in chronic empyema cavities might be bettered by antiseptic lavage, wide open drainage at the bottom would remain a necessity to prevent septic absorption until such moment as further plastic procedures were necessary to obliterate the rigid wall pleural space. Was it true that the routine postpneumonic acute empyema of civil practice which closes spontaneously in a large proportion of cases would do so more effectively with lavage than without? If such were the case lavage would again become as popular as it was twenty-five years ago. However this might be, one should not lose opportunities to convince one's fellow practitioners that when the cavity of an acute empyema does not close in due time, continued

lavage with any one of the many solutions which the war has occasioned will neither counteract the absorption from a badly drained cavity nor close such a cavity when prolonged infection has produced the characistic signs of chronic empyema. The war had afforded also innumerable contributions of instrumentation, technique, anesthesia, and the like. He had selected what appeared to him to be important problems for thoughtful consideration and application.

2. Thoracotomy from the Standpoint of Repair.—Dr. JOHN L. YATES of Milwaukee, Wis., presented this paper by invitation. He stated that a satisfactory method of performing thoracotomy, which Dr. Meltzer held to be so desirable, must provide for recovery with virtually unimpaired function, with transient distress and disability and with negligible danger. Recovery without materially impaired function was possible when the movements of the thoracic parietes were unrestricted, when the intrapleural negative pressure was within normal limits, and when the pulmonary elasticity was preserved. The most important factor in preserving these three necessities was the utmost restriction and limitation of pleurisy. Since the majority of thoracotomies were undertaken for the cure of pleurisy, and since pleurisy was the inevitable consequence of all thoracotomies and the most common cause of failure of this operation, it was the big problem to be considered. Thoracotomy from the standpoint of repair defined a method of operating which would permit a tissue healing compatible with the return of function. This entailed the following essentials: (1) An incision so placed that parietal mobility would receive the least restriction; (2) So that parietal healing should occur with the minimum of irritation and therefore with the greatest certainty; (3) Intrathoracic manipulations should be designed to reduce pleural irritation in so far as possible; (4) Differential pressure should be provided so that at the end of operation negative pressure was reestablished and with it the return of function of respiration and pulmonary circulation was guaranteed; (5) The nitrous oxide and oxygen method of pressure analgesia developed by J. T. Gwathmey was at the present time the method of choice; (6) Closure of lung after any intrapulmonary operation should be such that immediate function was possible, hence no mass suturing was permitted; (7) Closure of parietal pleura should be such that accurate serosa to serosa approximation was obtained without undue suture tension which was attainable best after a rib exsection; (8) Every thoracotomy was followed with an accumulation of fluid which was unmistakably evident by the second day. Primary drainage of the pleural cavity prevented the accumulation of this excess exudate; (9) Primary drainage of the thoracic cavity in the simplest form was a tube inserted intercostally in an airtight fashion and armed with a one-way valve. Primary drainage by this means was indicated at the end of thoracotomy whenever there was any likelihood of undue pleural irritation, and as this danger was more often present than absent, routine drainage was probably advisable.

3. Full Exploration of the Thorax in Recent Wounds of the Lung.—Dr. HOWARD LILIENTHAL of New York advocated a large incision in the seventh intercostal space, with a wide rib retraction by means of a powerful spreader. Through such an approach all parts of the pleural cavity could be explored, and if a detailed operation were necessary the wound might be further enlarged by posterior section of one or more ribs. In the majority of cases the rib cutting was not necessary, merely the wide incision and rib spreading. Through this opening even the wounded pericardium might be explored and sutured. When the operation was completed the wound in the thoracic cave could be easily closed by approximating the rib with pericostal sutures. A pleural suture was not required provided the edges of the pleural wound were turned outward and held while the ribs were crowded together. This operative method had given him great satisfaction in the evacuation hospital work. He did not believe that the resecting of the axillary portion of the fourth rib, which was a favorite thoracotomy of some surgeons, was as desirable, as less access to the remote portions of the lung could be obtained through it. In doing this wide form of thoracotomy he preferred some form of differential pressure. He gave choice to positive intrapharyngeal insufflation.

Dr. NATHAN W. GREEN of New York had observed, in reading the literature of the surgery of the lung and pleura, that many men recommended operating under local anesthesia because, in the first place, the patient could control the condition of the lung at the operator's request. Another reason was that possibly less poison was superimposed upon the already existing infection, with less poisoning of the leucocytes and consequent diminution of their phagocytic action, notwithstanding the large operation to be done. If one operating under local anesthesia attempted to take hold of the patient's lung, the patient would not permit it; he would complain bitterly of deep-seated pain. The best alternative was to use general anesthesia at the same time having substituted for the patient's volition an apparatus by which, so to speak, one could blow up the lung or hold the breath, or let it out. The apparatus that accomplished this was an apparatus for differential pressure. It was most important, when one was operating in the chest cavity, that he be able to control the volume of the lung, namely, the degree of expansion or of collapse. This in itself was the most positive reason why differential pressure should be used in thoracic surgery.

Dr. MEYER asked that thoracic surgery in civil life be considered principally. All recognized that under the stress of war the majority of our colleagues who had the courage to proceed actively in thoracic cases had to go in, the way they did, because apparatus were not at hand. But now we were confronted by the question whether it was correct, whether it was advisable to apply the experience gained during the war, near the battlefields, to civil practice. Was it advisable to say, because the experience had been gained in war surgery, that one *might* get along in this 50, or perhaps 40 to 45 per cent. of patients with injury of the lung who did not die on the battlefield without the use of apparatus, that the differential pressure method was superfluous—an unnecessary ballast?

Dr. HOWARD LILIENTHAL of New York had already gone on record in this meeting as to the necessity of differential pressure in operations opening the thorax. In addition he stated that if the thorax was to be widely explored, and if one did not have means of keeping the patient's respiration as nearly normal as possible by some form of differential pressure, there would be times when one would have to close the wound on account of the threatened asphyxia. It would be necessary either to close the wound or to make traction on the lung. Adhesions in the thorax were common, especially in the apex, and that was one reason for the absence of trouble in many instances in which no differential pressure was employed. Other cases were handled quickly, and for only a small part of the time was the lung entirely free so that it could collapse. It was not quite fair to judge differential pressure methods by the war surgery. In the latter class of work he had had with him a foot bellows and apparatus for intrapharyngeal insufflation. The method was easily learned by the nurse anesthetist. One did not need to have the most complete form of equipment. The danger of overdistention was slight, and often when the patient coughed or strained it would be noted that the lung expanded more completely and forcibly than one would dare to expand it artificially. With the chest open a manometer was necessary. In one case of gunshot wound of the chest, in which the bullet had entered below the left nipple and lodged between the ninth and tenth ribs, when the differential pressure was omitted there was clearly embarrassment of respiration, which was immediately relieved when differential pressure was started again. The apparatus used was only a Paquelin bulb with secondary chamber. The bullet was removed, and the lung disinfected, and the man recovered with scarcely a symptom. Even at the front one could always carry a Paquelin bulb. Dr. Heuer's results were certainly brilliant, yet one wondered whether possibly even a better record could have been made with the aid of differential pressure. In civil practice it was absolutely wrong and unsurgical not to be prepared with this simple expedient for saving life.

Dr. MEYER asked that those tell their experiences who had seen thoracic surgery well accomplished in civil life without differential pressure apparatus, and who had not observed any untoward results. This ought to be known. Perhaps on the basis of their favorable experiences it might be possible to throw overboard what was now considered essential.

Dr. CARL A. HEDBLOM of Rochester, Minn., had not had much experience with differential pressure in thoracic surgery. During the past year he had operated on a series of cases of chronic empyema, doing a decortication by the rib spreading exposure. He could not get Dr. Lilienthal's retractor, so he and Mr. Little had made one which he had found very serviceable. In these cases there was no respiratory difficulty even after the affected lung had been entirely mobilized. The thickened mediastinum made possible adequate functioning of the sound lung. In case of intrathoracic tumor he had used intratracheal insufflation with success. He had had no experience with pharyngeal insufflation, but the method appealed to him as very practical in cases in which things went wrong when operating under local anesthesia. Recently, in suturing the lung to the parietal pleura in a case of abscess he had accidentally opened the thin visceral pleura. He had no particular difficulty, but if he had had a pharyngeal insufflation apparatus for inflating the lung he would have been more certain of having securely sutured the lung to the parietal pleura.

Dr. JOHN A. HARTWELL of New York asked if the question did not resolve itself into physiological factors. In man when the chest was opened on one side the elastic fibres in its structure tended to force the air out of this lung and it collapsed. Graham had shown not only on the dog but on the cadaver, that the other lung also was influenced by the inrush of air. In other words, the mediastinum was not in the least fixed and the open pneumothorax transmitted its influence directly through it. If the opening on the one side were as large as the opening into the trachea the man would not get sufficient air into the two lungs to live comfortably. Therefore, by making the operative opening eight and a fraction square inches his ability to take air through the trachea would be so much compromised that he would be liable to collapse. In the dog, when the area of the opening in the chest equalled that of the open glottis, the dog suffered respiratory difficulty and promptly died unless differential pressure were used. Therefore, when it was necessary to do an operation in a case in which the normal lung pleura and mediastinum were to be dealt with, none of these structures being thickened or rigid, it would seem absolutely essential and without discussion that one must be able to force air into the man's lungs when he himself could not do it; in other words, when the operative opening approached eight square inches. The simple pharyngeal apparatus of which Dr. Yankauer had spoken in his paper, would meet all the requirements. The discussion had been confused because different conditions were being considered. Empyema or other inflammatory conditions presented an entirely different situation because the inflammatory adhesions and thickenings prevented the bilateral disturbance mentioned. Under these circumstances it was entirely justifiable to open one pleura without differential pressure, but, when possible, the simple pharyngeal apparatus with gas-oxygen should be at hand. Even if one made a large opening in the chest, as suggested by Dr. Lilienthal, and did not have a free intake of eight square inches, the man would be able to get sufficient air into his lungs to prevent disaster.

Dr. MEYER said this also seemed to answer in cases where there had been a long continued inflammation. He referred to the wide resection of the chest wall according to Schede, in cases of old chronic empyema, particularly in tuberculous patients. He was of the opinion that even there, where the mediastinum seemed to be fixed, if one operated on the left side and exposed widely the pericardium under atmospheric pressure, these patients must be assisted with the help of physical means in the first 24 or 48 hours, in order to get over the effect of the operation by this difference in the air pressure. He was convinced that with it one could tide these patients over the worst.

Therapeutic Hints.

Eczema.—In a discussion of the treatment of eczema Eisenstaedt gives measures which have been found safe, and in the majority of cases satisfactory in his own work. The external treatment of eczema, he holds, depends on the intensity, the stage of the disease, and its duration; in other words, on the clinical symptoms as interpreted from a pathological point of view. Those substances which produce irritation of the skin should first be eliminated from the patient's surroundings. In severe and generalized or extensive cases the patient should not wear starched linen or other articles of dress which rub against the inflamed parts. He should be confined to his room and should not exert himself, so as not to become overheated and thus produce hyperemia, which aggravates the condition. The skin should be treated with preparations which tend to alleviate the itching and to cause the inflammatory process to retrograde. There is no specific medication for the disease, each case requiring therapy based on the clinical picture at the time the patient comes under treatment. The physician should not change too rapidly from one type of medication to another.

Rickets.—John Laird, discussing the treatment of rickets, says when the time for prevention has passed, and the disease, through neglect or improper treatment, has made its appearance, the digestive organs must receive first attention. It is desirable that the bowels be gently cleared of all fermenting refuse matter, and a diet prescribed which will be suitable to the weakened condition of the stomach, while the child should be kept warm. When an excess of carbohydrates is given to the infant, fermentation with acidity readily takes place, and causes griping pains, often followed by diarrhea. This abnormal acidity in the results of stomachic digestion, on passing into the intestine, tends to neutralize the activity of the biliary and pancreatic secretions, and thus interferes with the digestion and absorption of the fatty elements of food, which are so necessary for the rachitic child. To correct this excessive acidity in the early stage of rickets is a matter of great importance. Laird, acting on the principle laid down many years ago by Ringer, that "acids given shortly before a meal check stomachic acidity," remembering at the same time the need that exists for phosphorus and lime salts in the rachitic child, has given with much success the following combination of remedies:

℞ Acid phosphoric dil. 3i
Liq. calcis saccharat. 3iss
Syrup. aurant. 3ii
Aq. chlorofomi. .....ad ℥iv
M. A teaspoonful to be given in a little water every third or fourth hour, shortly before meals.

A soluble phosphate of lime is formed with excess of phosphoric acid, and, on shaking, a clear solution is obtained, which is readily taken by children. When the digestive system is in good working order, cod-liver oil, in small quantity, either alone or combined with malt extract, will be of service. If given while the excessive acidity in the stomach prevails, it will only prove harmful.—*The Prescriber.*

Miscellany.

Professor Boeckel and Strassbourg University.—The old French medical school at Strassbourg before the German conquest in 1871 had as members of its faculty E. Boeckel, Sedillot, Küss, Stoltz, Schutzenberger, and numerous other men eminent in their day. Of all this number probably few or none survive, at least in a state of activity, with an exception in Boeckel, who with his brother was a distinguished operator. The surviving member was honored recently by the present French faculty on the occasion of his visit to Strassbourg and an address of welcome was delivered by Professor Teissier. The visit was described as a "holy pilgrimage" and Boeckel appeared in the uniform of a French military surgeon, he having, despite his age, served in the XIV legion. Surgeon General Delorme who had known him under the old French régime also made a speech upon this occasion, in the course of which he spoke of the great services of the old French faculty which had peopled Alsace-Lorraine with distinguished practitioners including many French army surgeons—Strassbourg having been the seat of the school for military practitioners. Two distinguished military alumni were Villemin, discoverer of the contagion of tubercle and Laveran of malaria plasmodium fame.—*Gazette des hôpitaux.*

Black Magic in France in the XVI Century.—To conjure the spirits of the dead and command infernal spirits which have never been incarnate are practices coeval with the world itself. In time these practices were used to exploit the credulous. Black magic goes in cycles and in the XVI century a cycle of great extent and intensity appeared in Europe. There were during these times as many as 30,000 alleged sorcerers in Paris alone and tenfold that number in the whole of France. The more these people were prosecuted the more they flourished. The widow of a marshal of France who evidently suffered from hysterical grand mal was burned alive in Paris. In such familiar episodes the accusation was often that the victim had bewitched people by wholesale. The truth appears to be that the victim's convulsions had caused imitative behavior on the part of young girls in convents, etc. Durodié in the *Gazette hebdomadaire des sciences médicales de Bordeaux* for February 8, 1920, xli, 6, in connection with this subject has given an account of an alleged demoniac, a young woman who in 1599 was well known in a certain quarter of Paris for her habit of convulsions. She was said to be possessed of three separate devils. She was regarded by the authorities as a victim and not as a sorceress and many attempts were made to exorcise the spirits. She even went before a board of mixed theologians and medical men and diverted them by the most extraordinary convulsive phenomena which included leaping and contortion, accompanied by lugubrious cries suggesting various animal species. Theologian Marius tried to calm her by speaking in Greek whereupon Medical Doctor Mareschal addressed her in Latin, putting certain subtle questions in that tongue. Marthe, the victim, was unable to reply, whereupon the board decided officially that she was not possessed. As she had intimated that she could answer better in another place, she was taken into a chapel where she was secretly watched. She had convulsions as before and was later found to be markedly anesthetic to the needle test. After some delay there was a public exorcism but Marthe with great agility broke away from the throng. She was recaptured and later said that the spirit had left her, but soon resumed her convulsions. Prolonged observation was then decreed during which her behavior was of the most placid type, so that she was pronounced a fraud. She was handed over to the custody of her father under the supervision of the courts.

History of Smallpox and Vaccination in Venezuela.—According to Rosales, variola was first officially shown to exist in this country in 1572, when it was enumerated with other endemic affections which attacked the public on a large scale. The disease had been brought to the country by a Portuguese sailor, and did not vanish until 1580. It reappeared in 1588, this time from New Grenada. It reappeared three times in the seventeenth and three times in the eighteenth centuries, and in 1658 practically killed off the slaves. In the nineteenth century there were many epidemics—so many that it is doubtful if the disease ever ceased outright. Since 1906, while the disease is never wholly absent, there has been no mass incidence. The Indians have always been the chief victims. It is said that the first attempts at vaccination were made in 1769, but this doubtless refers to the inoculation, not of cowpox, but smallpox. We do not hear of genuine vaccination until 1803 and in the following year Balmis, called the Spanish apostle of vaccination, visited Caracas with governmental authority and vaccinated many people. Very puzzling were several deaths of prominent people five or six or more days after vaccination without the least evidence of any local or general outbreak. There were four of these cases. Another subject, although vaccinated, died of smallpox contracted in the usual manner, the interval having evidently been too short for protection. Still another vaccinated subject apparently developed both affections side by side. The preceding were all vaccinated at the same time and place, by the arm-to-arm method. They are the more difficult to understand because several others showed the usual cowpox and were afterward immune to smallpox. We next hear of vaccination in 1818-19, when many subjects were vaccinated by the arm-to-arm method. No untoward events are mentioned, and an Englishman, Forsyth, seems to have been in charge, and to have been secured by the Federal Board of Health. In 1841-2 no less than 24,000 individuals were vaccinated. In 1865 fluid vaccine was first received from London. In 1881 vaccination was made compulsory in Venezuela. In 1897 a Pasteur Institute was established and vaccine was made in the country for the first time; and soon afterward, the supply being insufficient, a special vaccine institute was projected, but the war retarded the movement, and not until quite recent times has the Bacteriological Laboratory of the Board of Health taken over this duty. During the first half of 1919 a million persons were vaccinated. —*Anales de la Direccion de Sanidad Nacional.*

SOME PRINCIPLES SELDOM RECOGNIZED IN THE TREATMENT OF SYPHILIS AND THE SYPHILITIC.*

BY WILLIAM WASHINGTON GRAVES, M.D.,

ST. LOUIS.

PROFESSOR IN THE DEPARTMENT OF NERVOUS AND MENTAL DISEASES, ST. LOUIS UNIVERSITY SCHOOL OF MEDICINE.

Oh! Syphilis, when wilt thou be understood?
—Ricord.

IT is neither my intention to offer here any plan nor to laud any drug, but rather to discuss briefly some of the principles now utilized and other principles seldom recognized in the treatment of syphilis and the spyhilitic in any period of the infection. It seems to me that irrespective of the time that may have elapsed after infection, the same principles should govern our treatment of the individual, no matter what form of medication we may decide upon to administer to him. Since we have no certain means of knowing the termination of syphilis in individuals who have acquired it *in utero* or at some time after birth, all such individuals are here considered syphilitics.

Recognizing an individual to be a syphilitic, the questions naturally arise: How shall we treat him and over what period of time? In other infectious diseases our therapy should be, and usually is, founded on knowledge of the individual's health and disease tendencies as disclosed by a study of his family history; a study of his life, of his reactions to his environment, of his habits, of his occupation and on knowledge of his total physical condition. This principle seems axiomatic in its application to the treatment of disease whatever its nature may be. Strange to say this principle at the present time is not often recognized in the treatment of the syphilitic, since the treatment is based mainly on one seeming essential fact: the individual gives a positive Wassermann reaction. With this limited knowledge concerning him, so-called "specifics" are administered in the course of time until the Wassermann reaction becomes negative. The many negative Wassermann reactions in any period of the disease, relatively speaking, even in the presence of active manifestations of syphilis and the possible presence of disease other than syphilis in the syphilitic, render the use of this or any other laboratory sign wholly illogical as the essential indication for, or guide to, treatment.

*Read before a joint meeting of the St. Louis Neurological Society and the St. Louis Society of Internal Medicine, February 23, 1920.

There is no denying the fact that the present-day objective in the treatment of syphilis is the certain "cure" of the disease by chemical means; hence, in trying to carry out this objective, the syphilitic during his periods of treatment is often lost to view. As a profession we have never had much concern about him after the "cure" has been wrought, and never have we had so little concern as at the present time. Many of us are acquiring the habit of disregarding the syphilitic as an individual prior to, during, and after treatment, and of treating the positive Wassermann reaction rather than the individual. Such pernicious therapeutic principles can only have the effect of giving to the syphilitic an unwarranted sense of security and of commercializing the treatment of the disease. Mainly since the advent of the Wassermann reaction and arsphenamine, syphilitics are taught to believe themselves cured when the Wassermann reaction is negative, and are thus made to feel safe from further manifestations of the infection as never before in the history of syphilis. Many physicians believe, and consequently many individuals are taught to believe, that a positive Wassermann reaction is an indication for intensive treatment and that a negative reaction, in the absence of gross signs, is a contraindication for any treatment whatever. The syphilitic is thus becoming a sort of laboratory animal. Basing their propaganda upon such teachings and practices on the part of many in the profession, some laboratories are now commercializing the treatment of syphilis. Some of them are ready to take over the treatment of syphilis, not only in the early, but in the later, periods of the disease, so long as these are accompanied by a positive Wassermann reaction. Shall we blame laboratories engaged in such harmful and pernicious practices for reaping a commercial harvest gleaned from such practices when the Wassermann reaction is used so largely by the profession, both as an indication for, and as a guide to, the treatment of syphilis? Rather should we blame ourselves and pause to reflect on the natural history of this—*the most insidious of all diseases,* and during our periods of reflection ask ourselves at least three very serious questions:

1. Have we any justification for the present-day teachings and practices in the treatment of syphilis?

2. Are our brilliant so-called "cures" now, or have they ever been, with but few exceptions, other than symptomatic cures?

3. Have we any biological or clinical evidence justifying the conclusion that the favorable influence of remedies in human syphilis is dependent upon any other factor than their influence on the defensive mechanisms inherent in the syphilitic?

Each of these questions may, in a measure, be answered by recalling the natural history of a syphilitic infection, either aided or unaided by remedies. Such symptoms as malaise, indisposition, general bodily discomfort, pain now here and now there or definitely localized, mental and physical inadequacy, torpor, gastric disturbances, dizziness and slight elevation of temperature occurring in some individuals usually six to twelve weeks following the infection, are considered *constitutional manifestations* or the reaction of the whole organism to the spirochetal invasion. These symptoms usually become less pronounced and subside in a short time, whether the individual has treatment or not; the local manifestations, if any have occurred, disappear, and, as a rule, in the course of time a relative degree of health returns. The patient thereafter considers himself cured if he has had what his physician believes to be adequate treatment; or, if his disease has not been recognized by himself or his physician, he remains in any case oblivious to it and enters the so-called *latent periods* of the disease. In some individuals such periods develop very early; in some very late, and in others, fortunately in only a few, not at all. Arbitrarily fixed, the so-called latent periods begin from one to five years after infection. Careful inquiry into the personal histories of those known to be syphilitic during these periods and even of many of those to whom we have given what we consider adequate treatment, discloses in many, breaks in health which can often be interpreted as recurrences of the constitutional manifestations of the disease.

When we seriously study the recurring constitutional manifestations of syphilis, we shall find them to be by far the most frequent and among the more important manifestations.[25] They are among the more important, because they seem to be Nature's warnings and seem to represent the reactions of the whole organism to the virus—its struggle to overcome the infection or to establish a better tolerance for it. It is a clinical observation, not always appreciated, that during the so-called latent periods of syphilis its more serious manifestations seldom develop without warnings. Our recognition of recurring constitutional manifestations will often enable us to aid Nature in her efforts and thus prevent, by well-directed therapy in many individuals, the more serious manifestations. Clinical experience in the natural history of syphilis, which has been accumulated by many workers, should lead us to the realization that scarcely any organ or tissue may remain exempt throughout the so-called latent periods of the infection; that its frank manifestations may occur or recur at any time in the life of the infected individual, however thoroughly we may have treated him in the earlier periods of his infection; that its subtle physical signs, such as cardiovascular changes, alterations in reflexes, in the special senses, sensation and pupils, pallor and pigmentations, etc., etc., may develop insidiously in many syphilitics in the course of years—in some early, in some late—after infection with or without definite subjective complaints; that studies of the life histories of many syphilitics show that they are often incapable of reacting in a normal manner to the stresses and strains of existence; that because syphilis is a chronic infectious disease, not a few of its subjects are individuals of lowered general resistance; that some syphilitics are potentially, and possibly inherently, either paretic or tabetic, or both; that a large number of apparently healthy syphilitics, however thoroughly we may have treated them, show positive Wassermann reactions and most of them definite physical signs after sufficient time has elapsed following so-called "specific" treatment and that we have no definite means of knowing when the one-time infected individual is free from his infection. It is particularly the insidious development of definite physical findings and the recurrences of constitutional manifestations in many individuals in the so-called latent periods of the disease which should cause us seriously to question the reality of such periods and never to lose sight of the constitutional nature and chronicity of a syphilitic infection. All clinical evidence is in support of the idea that the virus, once it has invaded the tissues of the body, so long as it remains, seldom, if ever, becomes wholly dormant—latent.

If the teachings of clinical experience be accepted, are they not in conflict with the idea of latency—an idea in which we have heretofore implicitly believed? The idea of periods of *relative tolerance* for the virus, meaning thereby an *excellent*, a *fair* or a *poor* resistance of the *whole* or *parts* of the organism but seldom an absolute resistance, seems to be a better conception: one more in accord with clinical experience and the natural history of the disease than that of latency.[26] The recurrence of constitutional manifestations and the development of subtle, though *definite signs* during the assumed periods of relative tolerance, are doubtless due to many factors, chief among which seem to be the *inherent resistances* of the tissues of the individual, his habits, his mode of living and his environment. If the first factor (inherent resistances) is defective and from circumstances becomes more so, the disease may pass beyond our control. The other factors (habits, mode of living and environment) may in many cases be controlled, and the first (inherent resistances) may often be improved by attending to the others with the result that a good degree of health can be established in the vast majority of syphilitics. But our control of any one or of all of these factors is seldom absolute; hence as a working clinical axiom it may be asserted that the individual, who has contracted a syphilitic infection either in utero or after birth, remains thereafter one of lowered general resistance.

When laboratory aids to diagnosis are used as evidence of cures, both the physician and the patient are in positions most insecure: The physician is led to feel that he need no longer be concerned about the *cured* patient, and the patient is led to feel that he need no longer be concerned about his disease. The patient may thereafter live as he will. He may marry, of course, since he is cured and this too with medical sanction! There is no denying the fact that many in the profession believe in their ability to cure syphilis wholly by chemical means, and they naturally grasp and utilize to the fullest extent all evidence which may be utilized as proof of such cures. It has, therefore, been easy to accept as evidence of cures, and without criticism, the evidence afforded by the beneficent diagnostic aids,

which have come to us in recent years through the laboratory. In this connection it may be mentioned that for years we have pointed with pride to the progeny of syphilitic parents—parents whom we have treated thoroughly and well. When the progeny disclosed neither Hutchinsonian teeth, interstitial keratitis, bone, joint, mucous membrane, or skin manifestations we believed we had found convincing evidence of our cures in the parents. Fortified by the absence of manifest signs of syphilis in the progeny and with a negative Wassermann reaction in the parents, many of us have found ample justification for the present-day teachings and practices in the treatment of syphilis. Those of us who have found ample justification in such evidence will continue to find it; will continue to be blinded by the glare of our therapeutic triumphs until we begin more generally to study the life histories of syphilitics, including those formerly treated thoroughly and well by us; until we begin to study the life histories of their wives and children, and until we begin to make intensive physical examinations of the several members of the family. A few studies have been made in this direction and some of these are recorded in the voluminous literature of syphilis.* Personal studies in these directions will appeal to the investigator stronger than words, and when made in sufficient numbers will cause many in the profession to be less certain about their ability to cure the disease by any drug or combination of drugs yet known to us; to have less confidence in the present-day teachings and practices in the treatment of syphilis; to recognize most keenly that most of our cures are symptomatic cures; to be less willing to give sanction to the marriage of a syphilitic, and to appreciate more fully than we do to-day that syphilis is *a racial poison* unparalleled by any other.

No one has ever contended that syphilis is beneficial for the race; on the contrary, it is coming to be universally recognized that syphilis is a germplasm or racial poison. We have heretofore considered it a racial poison only when the parents have been untreated or inadequately treated, and we shall continue to do so until we fully recognize syphilis as *a possible germ-plasm poison and as a familial disease.* When we find evidence of syphilis in the husband, wife or in both, we should adopt the principle of studying all of the progeny. In doing so, we should not content ourselves with serological studies and with searching for the usual signs of congenital syphilis in the progeny, but we should apply in these studies the knowledge we now possess in reference to certain laws of heredity, and in doing so ask ourselves these questions:

Is syphilis a germ-plasm or racial poison only in the progeny of the untreated or the inadequately treated; and do the progeny of the adequately treated wholly escape its blighting effects?

We know of no standard of normality by which we may measure individuals in reference to total development and adaptability to environment, except that standard disclosed by the parents or more remote ascendants. It is generally accepted as the rule in human and animal breeding that, in the absence of disease factors, "like begets like" in total development and adaptability to environment, and that healthy parents beget children comparing favorably with each other and with their parents in these directions. "A chip off the old block" is expressive of the expectation usually realized in the offspring in healthy human breeding. The parents and more remote ascendants, therefore, serve as firm foundations—as *biological standards*, by which the individuals of the race may be measured. I have repeatedly emphasized the importance of using such standards in our studies of the effects of disease in parents on the offspring, and have called these *comparative clinical and anthropometric methods.* When such methods are applied in syphilitic families, it is rare, indeed, to find a child meeting the usual expectation of healthy human breeding. To become convinced of this fact, one need only to make such studies in a few families wherein syphilis is known to be present in one or both parents and as a control in a few families where syphilis, other disease, alcohol, and other poisons can be positively excluded. Such studies will show the relative infrequency of the usually recognized signs of congenital syphilis in the progeny of syphilitic parents, but will show in many of such progeny *deviating characteristics* in total development and adaptability to environment, and that even the progeny of those whom we believe to have been adequately treated seldom wholly escape the blighting effects of the parental infection.

A prominent dermatologist, recently lauding arsphenamine, expressed the belief that by its use the period of treatment might be shortened and that marriage of the syphilitic might not be so long deferred. Our therapeutic triumphs have made us optimistic in the belief in our "cures," and the proof of this fact is best evidenced by the attitude of many of us toward the marriage of the syphilitic. We are at the same time most pessimistic about the future of individuals who fail to remain under rather constant treatment until the Wassermann reaction has become repeatedly negative. Before the Wassermann era, clinical experience had taught us that the syphilitic should remain under treatment three, four, or five years, and since this era, so far as we know, the nature of a syphilitic infection has not changed. It is safe to say that not more than 10 per cent.[21 26] of the syphilitics who come under medical observation in the early periods of the disease receive what is believed to be adequate treatment; hence the number of adequately treated cases is an insignificant number when compared with the number we believe to be inadequately treated and with the number who either ignore or are unaware of their infection. The truth of the matter is that no one can say when a syphilitic is cured, since clinical experience teaches that in any period of the life of the infected individual incident to the lowering of general or local resistance or independently of the one or the other, active manifestations may occur or recur, and these, too, in some, irrespective either of the manner or the length of treatment. Neither can we say when the syphilitic is no longer capable of conveying the disease to his wife and, if so, probably through her to his child. But this we do know: Serological studies of the one-time-known-to-be syphilitic are in accord with clinical experience in showing that a relatively large

*The most complete family study thus far published appears to be that of W. Raven (*Deutsch. Zeitschr. f. Nervenheil*, 1914, vol. 51, p. 314).

number of supposedly adequately treated individuals are still syphilitics; that some of the wives of such syphilitics are also syphilitics, and that some of the progeny of such syphilitic parents are likewise contaminated. Believing in our cures and resting contentedly in the presence of apparent good health, in the presence of a negative Wassermann reaction and in the absence of active manifestations, we come to regard the one-time-known-to-be syphilitic as cured, and thereafter he is no longer the object of medical observation and study. If he is cured certainly he may marry, since there can be no danger to consort or progeny; and if we later look at the consort and progeny at all, unless we find the usual gross manifestations, we construe the absence of such as evidence of the value of our therapeutic endeavors.

A consideration of the natural course of a syphilitic infection, modified as it often is and doubtless cured in some by treatment, appears to afford neither justification for the present-day teachings and practices in the treatment of syphilis nor for the belief that our cures in most cases are other than symptomatic, but it definitely points to the conclusion *that the same mechanisms of defense become operative in the presence of a syphilitic infection as in any other infection.* If the same mechanisms of defense are at the bottom of our so-called cures, then we have, in these mechanisms, rational foundations for our therapy. These mechanisms of defense (inherent resistances) may be so active in some individuals that they speedily overcome the spirochetal infection unaided by any medication whatever. These mechanisms of defense (inherent resistances) are, therefore, the syphilitic's most valuable asset in combating his infection. If this be true, then they should be most zealously guarded both by the patient and the physician: by the patient in his manner of living and in his cooperation with his physician; by the physician in his advice, in his use of drugs, and in his avoidance, if possible, of every weakening influence on these mechanisms.

Clinical experience daily teaches the beneficent effects of our remedies in the relief of some syphilitic manifestations, but it also teaches that it is possible through over-treatment to do harm. A medieval dream, renewed with delight by many in the profession on account of the discovery of arsphenamine, has proved in the light of clinical experience to be largely iridescent and founded upon theoretical rather than upon biological conceptions. Our medicinal treatment of syphilis is still largely empirical, and it will aid us and in turn it will aid the army of syphilitics if we recognize this fact. Clinical experience, as well as the natural history of human syphilis, teaches that in arsphenamine, mercury, iodides, iron, etc., etc., we have *remedies* merely—not *cures* in themselves of a syphilitic infection. When these drugs act beneficially in the treatment of syphilis, they appear to act as stimulators of the defensive mechanisms in man rather than as direct spirocheticides in him. So long as one may so adjust the remedy to a particular individual without over-stimulating and thus weakening or paralyzing his defensive mechanisms, remedies have an important place in the treatment of syphilis, but we must remember that our remedies are like two-edged swords—*they can be made to do great good* and *they can be made to do great harm.* It seems to me that the least important thing to do for a syphilitic, relatively speaking, is to give him medicine. I say *least* important, because the giving of medicine supplies only one of the many conditions underlying a well-directed therapy, regardless of the nature of the disease. The natural history of treated and untreated syphilis teaches that notwithstanding the absence of a natural immunity to syphilis in man, he, nevertheless, seems to be possessed of unusual inherent resistances to, or of a natural tolerance for, the virus of syphilis. If this be true, we may deduce two fundamental principles in the treatment of the syphilitic—first, *the principle of making an accurate survey of the individual's inherent resistances through a study of his family history, of his past and present reactions to his environment and of the sum-total of his physical condition;* second, *the principle of strengthening the individual's inherent resistances by every possible means throughout his natural life.* Both these principles seem to be neglected when the Wassermann reaction is used as an essential indication for and a guide to treatment, when we blindly base our therapy on so-called specifics and when we ignore the teachings of clinical experience in the natural history of syphilis.

Remembering the protean manifestations and the chronic and insidious nature of a syphilitic infection and our inability to know its termination in any individual save by reinfection, are we not for these reasons justified in holding firmly to the principle—that a known syphilitic should be the object of medical observation and study throughout the remaining years of his life?* Does not accumulated clinical experience in the problems of syphilis justify the general acceptance of this principle? This principle will meet with many objections, chief among which will be that such concern on our part about the disease will unnecessarily alarm patients and make of them *syphilophobics.* We do not hesitate, however, to educate our tubercular patients, to speak frankly to the individual about his organic heart disease, to keep the chronic nephritic under constant observation, to be solicitous about the patient with diabetic symptoms, and our frankness in such conditions leads only to good, beause we thereby educate and thus secure the earnest cooperation on the part of such patients. Then why have we been less frank with syphilitic patients or less solicitous about them when all clinical experience teaches that we are dealing with an infection in many individuals, the chronicity of which can be compared with no other prevalent, communicable disease? The answer is: *Our therapeutic triumphs have heretofore blinded many of us to the teachings of clinical experience and the natural history of treated and untreated syphilis.*

No man can deny the brilliant, one might say miraculous, results of our so-called "specifics" in the prompt relief of many of the manifestations of syphilis, but let us hesitate to interpret these results as other than symptomatic cures. The prompt disappearance of some symptoms and some physical

*By observation and study is not implied constant medication or any medication whatever after the first three to five years, unless a complete restudy of the *whole individual* at least once in each year should indicate further medicinal treatment.

signs and the natural history of treated, as well as untreated, syphilis should convince us that the same mechanisms of defense are at work in the human organism in the presence of a syphilitic infection as in any other infection, and that our remedies *do not act directly as spirocheticides and sterilizers, but rather as stimulators of the defensive mechanisms inherent in the host.* Let us aid these, if we may, through drugs, but while we are trying to do so, let us not forget that these mechanisms are the syphilitic's most valuable asset in his struggle with his infection. Let us educate him in the nature of his infection—give him neither false security nor undue alarm about it. Let us teach him that right living and drugs are equally important and that constant vigilance throughout his life is the price of his safety. Let us make him feel, if he will thus live, that in all probability he will lead a relatively healthful and useful life in spite of his infection—a more healthful and useful life than he who lives riotously, even though he be free from such infection. Let him know that clinical experience teaches that the syphilitic need deny himself nothing that life affords when used in moderation, but for the welfare of his potential mate and descendants—for the welfare of the race—that he should gladly deny himself the privilege of marriage.

With such therapeutic principles, as herein discussed, to guide us, we shall find more to do for the syphilitic than in trying to convert his positive Wassermann reaction into a negative one; we shall then think more about the individual and less about his disease; more about strengthening his inherent resistances to, or increasing his tolerance for, his infection, and to this end we shall find many ways in addition to the use of remedies. Confessing the limitations of our measures and remedies, yet fully conscious of the great good to be derived from them, may we not through a more general recognition of their limitations and through the education of the masses more nearly approach the *ideal cure*—the prevention of syphilis?

When we shall become less certain about our cures of syphilis—think more about the individual, the consort and progeny—may we not then reasonably anticipate the dawn of a better day for the syphilitic and the dawn of a brighter day for many of the race?

THE SIGNIFICANCE OF THE DIASTOLIC PRESSURE.

BY L. F. MACKENZIE, M.D.,

NEWARK, N. J.

ASSISTANT MEDICAL DIRECTOR THE PRUDENTIAL INSURANCE CO. OF AMERICA.

WHEN Dr. Crawford honored the writer by an invitation to read a paper on Blood Pressure at this meeting of the American Life Convention, he suggested special attention to the Diastolic Pressure, and, if possible, mortality ratios of entrants with both large and small pulse pressures.

A review of our claim cards showing pulse pressure satisfied us that the numbers with this pressure under 25 mm. or over 50 mm., were so small that statistics prepared from them would furnish very inconclusive information. Further investigation

along this line was abandoned. It will consequently be necessary, in order to comply as nearly as possible with the invitation, to discuss the diastolic from other angles, in this way, and through comparison with the systolic, trying to arrive at some definite conclusions as to its significance, normal limits, and range.

Prior to 1905 estimation of the diastolic pressure was very unsatisfactory, except with the use of instruments too cumbersome and intricate for office or general work. Readings determined by palpation, while reasonably accurate, and sufficiently so for everyday estimation of the systolic, were far from satisfactory in fixing the diastolic. Interpretations of the point of maximum oscillation differed widely. The diastolic, in consequence, was given little consideration and very meager data were collected. When, in the year above mentioned, Korotkow introduced the auscultatory method, estimation of this pressure was much simplified, more general interest in it was aroused, and to-day it is recorded almost as often as the systolic, though by many not yet as accurately taken. Improvement in this respect is noted and now diastolic readings at both the fourth and fifth points are frequent.

The diastolic pressure at the present time is considered by the majority of observers the more important. Certainly no blood pressure record is of great value without it, as judgment based on the systolic alone may be very misleading.

The significance of the diastolic and pulse pressures, in the absence of sufficient statistical data to justify definite conclusions, must be based on what we have of these, but more important, on known physiological and pathological changes affecting or involving the circulatory system. We, therefore, ask your indulgence while we recall a few fundamental facts before directing your attention to a study of our available diastolic data and the fourth phase.

The factors controlling the circulation of the blood are exceedingly complex, and their fine and intricate adjustments admit of wide variations of pressure in health, and of marked compensations in disease. They may be considered in a broad way under two headings: 1. Nervous, which (a) act directly on the heart and (b) directly on the arteries and to a less extent on the veins. 2. Biochemical substances produced in (a) the endocrine glands, (b) in the body tissues, as a result of increased activity.

1. The nerve control appears to be the more important of the two, and for descriptive purposes may be divided into two groups, although intimately associated. They are, first, the vagus, accelerator and depressor nerves to the heart, and, second, the vasomotor, constrictor and dilator to the arteries.

Two of these appeal to the writer as worthy of special mention. The first, and most important, is the vasomotor control of the splanchnic vessels, which constitute a great reservoir for the blood and which through contraction or dilatation determine, to a large extent, the height of the blood pressure, particularly the diastolic, and the volume of blood in the systemic circulation. The second, important, but not very often mentioned, is the depressor nerve which, when stimulated by strain from increased pressure in the heart or aorta, occasions relief through central stimulation of the vagus, resulting in slowing and decreased force of the heart.

2. Biochemical substances derived from (a) the endocrine glands (b) tissue activity, as intestinal putrefaction. (a) The hormones from the ductless glands, particulraly the adrenals, thyroid, and pituitary, exert their influence by action on the heart and arteries. Those from the adrenals and pituitary have somewhat similar action, increasing cardiac tone and rate, constricting the arterioles and raising peripheral resistance with increased diastolic and systolic pressures. Those from the thyroid, on the other hand, have an opposite effect, dilating the peripheral vessels, increasing heart rate, through stimulation of the accelerator, but not tone. The diastolic and systolic pressures, therefore are lowered. The hormones of the adrenals and pituitary on the one side, and the thyroid on the other, have opposing actions, so that failure of the thyroid secretion results in increased pressure.

(c) Intestinal putrefaction with absorption of toxic products thus formed, is believed to result in constriction of the arterioles and increased resistance. Many abnormal conditions, either acute or chronic, influence the blood pressure in a manner more or less profound, and it would seem this influence is chiefly exerted on the diastolic in a majority of cases. Examples of this might be multiplied. We will let a few suffice. First, the acute infections, after the early sthenic stage, show more or less loss of vasomotor tone, lowered diastolic, weakened heart muscle and lowered systolic. If the heart has sufficient force, and rate, and lack of arterial tone is not too great, it may be able to overcome the vascular failure. The increased rate and force of the heart, however, are necessary far more for the maintenance of the diastolic, than the systolic. We believe recovery in this class of diseases and prolongation of life in many others is dependent on the diastolic, a sufficiently high level of which is essential for cardiac nutrition. This will be referred to later. Another instance, but with opposite effect, is that of autointoxication from putrefaction of material in the intestine. Abnormal products from this cause, absorbed and circulating in the blood, irritate the arterioles, resulting in constriction with increased peripheral resistance and higher diastolic. The systolic is also raised, but chiefly, if not entirely, on account of the extra effort put forth by the ventricle to overcome the increased resistance. We believe that with heightened diastolic, the volume of blood and heart tone being the same, the systolic is always raised from increased effort, and that the diastolic instead of following the systolic, as has sometimes been said, really determines its height in such cases.

Broadly speaking, abnormal blood pressure cases may be placed in one of two groups. First, those with changed diastolic pressure with accompanying and often more marked change in the systolic. This group is the result of variation in peripheral resistance. Second, those with little or no change in the diastolic but increase or decrease in the systolic as a result of change in cardiac action. Briefly, the diastolic is mainly the result of arterial tone and changes in it arise from changes in the latter. The systolic is the result of cardiac energy

put forth, and is largely based on the height of the diastolic.

Many conditions affect cardiac action and effort that have little or no effect on the arteries. Those affecting the arteries are fewer in number. The diastolic is, therefore, less subject to frequent and marked variation as arterial tone is more stable. When changed, however, it returns to normal more slowly. Increase in this pressure thus throws more constant and effective strain on the arteries, and ventricle leading to failure of elasticity in the former, and hypertrophy followed by dilatation of the latter.

Before leaving this part of our discussion, we wish to refer especially to that condition which is particularly indicated by changed blood pressure, and which is of such vital importance in our work. We refer to arteriosclerosis involving the renal blood vessels, and constituting the primary and only impairment of these organs which leads to marked change in pressure which is constant. Here both diastolic and systolic reach their highest readings; the diastolic from greatly increased tension in the periphery and increased pulse pressure; the systolic from hypertrophied left ventricle with much increase in force and effort to enlarge the pulse pressure that sufficient blood flow through the kidneys may be maintained.

We think we have shown above the possibility of wide variations in blood pressure readings. A few of what seem to us the more important factors have been briefly and imperfectly referred to. We would like now to consider the heart, which is the main compensating factor, provided the supply of blood is maintained. This most wonderful of all pumps, under the influence of the nervous system, and stimulated by arterial and venous pressures, runs either fast or slow, or with increased or diminished force to meet the constant and ever-varying changes to which it is subject. Volume of blood and peripheral resistance remaining the same, increased rate or force or both, raise the pressures, while diminished rate and force lower them. Lowered peripheral resistance, blood volume the same, calls for increased cardiac work through increased rate and force to maintain primarily a sufficient diastolic. Increased peripheral resistance, when temporary, results in slowing and decreased force of the heart. The variations possible are many with a mechanism so able to adapt itself to changing or changed conditions. It possesses the power, not only of a pump, but of a safety device. Its nutrition is, therefore, a matter of vital importance, and as the nutrition is dependent on a sufficient diastolic level, the importance of this pressure is at once manifest. When too low, the heart muscle is under-nourished and circulation impaired or stopped. When too high, the volume of blood forced into the heart wall is increased, adding additional strain to an already overworked and hypertrophied organ. Degeneration and failure are inevitable as a result. We are convinced that ventricular hypertrophy is the result far more of the constant necessity of overcoming a high diastolic, than of the intermittent effort required for sufficient pulse pressure, a pressure so essential to the nutrition of the tissues.

At the 26th Annual Meeting of the Association of Life Insurance Medical Directors, we read a paper prepared from an analysis of the blood pressure readings submitted to the Prudential Life Insurance Company of America. There were 18,637 cases with systolic readings and 5,018 with both diastolic and systolic. As a result of this study we concluded that the average systolic pressure rose gradually as age advanced from 119 mm. Hg. at ages 15 to 19, to 139 mm. at ages 65-66, the average for all ages being 125 mm. The average systolic was 2 mm. less under age 40 than for ages 40 and over. The average range was shown to be 30 mm. or 15 above and 15 below the averages at the different ages. The average low limits were thus for ages 15-19 104 mm. rising to 124 mm. ages 65-66. The high limits progressed from 134 mm. at the younger to 154 mm. at the older ages. "It was felt, however, that a pressure somewhat below the low limits is not usually as serious an impairment as one equally above the high limits." Since this was written, Dr. J. W. Fisher, Medical Director, of the North Western Mutual, has found a very favorable mortality experience among those with low systolic pressures. We now consider with great leniency all low systolic readings where the diastolic pressure seems sufficient and the pulse pressure is not under 25 mm. We further showed there was a rise in systolic pressure with increased pulse rate corresponding to 1 mm. for every increase of 5 pulse beats. An increase in this pressure in heavy weights was also observed, being 3 mm. above the average in those 20 to 29 per cent. and 4 mm. in those 30 to 39 per cent. overweight, age and height not considered. Height had little or no effect, the pressure being but 1 mm. less under 5 ft. 7 in. than at 5 ft. 7 in. and over.

We have presumed to give the foregoing systolic data as we think, from further study, the systolic is to a considerable extent indicative of what occurs in connection with the diastolic. We have, of course, considered averages of normal lives.

That a distinct relationship exists between the two pressures was indicated by our analysis of the 5,018 cases previously mentioned. This showed that the increase in the diastolic, as age advanced, corresponded closely with that of the systolic. The pulse pressure remained practically constant through the different age groups, though slightly smaller (1 mm.) on the average under 40 than for 40 years and over. The increase in the pulse pressure as age advances seems to be the result of less rapid rise in the diastolic, which is to be expected in connection with the natural changes—thickening and loss of elasticity—taking place in the arterial walls. The following figures, Table I, suggested the above comments:

TABLE I.

Ages.	Cases.	Average Systolic.	Average Diastolic.	Average Pulse Pressure.
15-29	3569	125	89	36
40-66	1449	130	93	37
15-66	5018	126	91	36

We felt in 1915 when preparing this table the diastolic readings were higher than would be reported when more experience had been acquired by our examiners and the same method and point used

by all in taking the diastolic. The figures in Table I were obtained partly by auscultation and partly by oscillation, so are possibly close to an average between the 4th and 5th points. Our thought at that time seems borne out by the figures given in Table II.

TABLE II.

Ages.	Cases.	Average Systolic.	Average Diastolic.				Length of Phase.
			4th Point.	Pulse Pressure.	5th Point.	Pulse Pressure.	
15-29	472	122	85	37	79	43	6
30-44	1106	125	88	37	82	43	6
45-66	257	131	91	40	85	46	6
15-66	1835	125	88	37	82	43	6

The number of cases in this table is small, but the great majority were examined by thoroughly competent physicians. The readings were all taken by auscultation, and almost all subsequent to those referred to in Table I. The steady rise in the diastolic is again seen, as also its relationship to the systolic. The age grouping, however, indicates the increase in pulse pressure, and less rapid rise in the diastolic takes place after 44 years of age, when vascular changes usually set in and advance. It will also be noted that the figures for the diastolic at the 4th point are lower by 3 mm. and at the 5th point by 9 mm. than in Table I.

It is our opinion that these figures represent very closely normal diastolic averages even when taken at the 4th point, which are in this table slightly higher, at the 4th point than normal, as will be explained later.

An attempt was made by us in 1915 to determine the diastolic range. It was then stated that the total range was 36 mm., or 18 above and 18 below the average. We ventured the opinion, "That the diastolic range should be greater than the systolic seems hardly possible, as this pressure is more constant and less influenced by emotion." We are still of the same mind, and believe the diastolic range averages less than the systolic. We know of no figures to verify this, but feel pretty confident it is strictly in accord with physiological laws governing the circulation.

Were 36 mm. to be taken as the range with 18 above and 18 below, we would get the following high and low diastolic readings based on Table II.

Ages.	4th Point.			5th Point.		
	Low.	Average.	High.	Low.	Average.	High.
15-29	67	85	103	61	79	97
30-44	70	88	106	64	82	100
45-66	73	91	109	67	85	103
15-66	70	88	106	64	82	100

Probably a range of 24 mm. is nearer the truth, and the high and low limits that it is wise to consider normal may be obtained by adding 6 mm. to the low (5th point) and subtracting the same number from the high (4th point) above given. If we now use the 4th point to establish the possible high and the 5th for the possible low we find using a 24 mm. range:

Ages.	4th Point. High.	5th Point. Low.
15-29	97	67
30-44	100	70
45-66	103	73
15-66	100	70

This amounts to a range similar to that for the systolic and is certainly liberal. Reasoning along this line, it seems safe to affirm that any diastolic pressure, at any age, under 60 mm. or over 103 mm., is abnormal if constant.

Lest it be thought we are disposed to adhere too strictly to rules based on statistics, we wish to state our belief that the systolic, diastolic, and pulse pressures may show wide variations in health, wider even than any figures we have given would seem to warrant. It is only when these variations from the averages are constant that we regard them as indicative of disease.

Many of the averages given as normal for the systolic were based on readings taken by palpation. It is now thought that five millimeters may in good risks be added to the high limit for any age when the pressure has been taken by auscultation and such averages used.

Figures decidedly outside the limits above shown are constantly reported but are not usually considered cause for immediate action in otherwise insurable risks. Additional readings confirming or correcting them are secured and careful urinalyses, chemical and microscopical, obtained when the pressures run close to or over the high limits. These precautions seem to us more necessary with diastolic departures from the strictly normal than with systolic. The systolic may vary to such an extent under emotion, nervousness, muscular strain, etc., that in our judgment we may usually disregard it when the diastolic is normal for the age and the applicant normal in other particulars. However, pulse pressures over 60 mm. or under 25 mm. are cause for close scrutiny of every other feature, and usually make at least one additional observation and special questioning of the examiner advisable.

Our knowledge of and confidence in the ability of the examiner are very important factors in estimating the readings given. In our experience it happens occasionally that very extraordinary pressures are submitted by less experienced examiners. Such readings as 120 diastolic and 130 systolic disturb our confidence in the ability and progressiveness of an examiner much more than they do in the insurability of the applicant, and, with the systolic normal, may be disregarded as far as acceptance of an otherwise good risk is concerned. Fortunately the number of doctors recording such readings is decreasing. We believe there should be none, and that these faulty readings cast a serious reflection on the physician reporting them.

A matter of considerable interest in our work, not only from the scientific side but also the practical, is the point at which to take the diastolic pressure. Some have claimed the 5th point or disappearance of all sound is the one to use, while probably more prefer the 4th point where the tone changes. That the 4th point represents the true diastolic pressure seems to have been established.

Determination of this point, however, is not always easy and at times is impossible. The point of disappearance, we think, is more frequently given correctly.

In establishing normal pulse pressure limits the length of the 4th phase and the most satisfactory point at which to take the reading have to be considered. The following questions present themselves: 1. Which point is the most desirable at which, for insurance purposes and in general practice, to take the reading? 2. If the 4th point, is it uniformly determined and reasonably accurate? 3. If the 5th point, what is the average fourth phase and how great an error is made when using this as the index? 4. Are departures from the average due to too high estimation of the 4th point or too low of the 5th, or to both? 5. How frequent are these departures? 6. How great are they? 7. Are they actual or simply apparent, due to individual interpretation?

Dr. W. A. Jaquith, Medical Director of The Prudential Insurance Company of America, in a paper read at the 29th Annual Meeting of the Association of Life Insurance Medical Directors, expressed the following opinions: 1. There are decided differences in the average readings by different examiners. 2. Age is certainly not a factor. 3. Variations have largely resulted from differences in individual interpretation. 4. The 4th point is shown to be more liable to incorrect estimation than is the 5th. 5. The 5th point thus appears to us as the one at which, for the sake of uniformity and accuracy, we should ask our examiners to take the diastolic reading.

The doctor has kindly permitted me free use of his paper and consented to additions to the tables already presented by him.

This report was based on an analysis of the blood pressure readings taken by 53 selected examiners in 754 cases.

"The 4th point could not be determined by 6 (11.3 per cent.) examiners in 8 (1.06 per cent.) cases."

The present analysis of 1,835 cases reported on by 219 examiners includes those used by Dr. Jaquith.

TABLE III.

FOURTH PHASE BY PERCENTAGES AND EXAMINERS

Examiner	Cases	Phase 2-6 mm.	Phase 7-8 mm.	Phase 9-10 mm.	Phase Over 10 mm.
A	48	52.1	35.4	6.3	6.3
B	31	87.1	12.9	....	....
C	181	98.9	..	0.5	0.5
D	37	70.3	16.2	8.1	5.4
E	159	97.5	1.9	0.6	....
F	30	43.3	30.0	6.7	20.0
G	41	85.4	7.3	7.3	....
H	165	82.4	10.3	6.1	1.2
J	31	61.3	19.4	9.7	9.7
K	42	42.9	7.1	47.6	2.4
L	31	93.5	6.5	....	....
Combined.	799	83.2	8.8	5.8	2.3
All others.	1036	68.5	12.3	11.5	7.7
All combined	1835	74.9	10.7	9.0	5.3

The examiners, eleven in number, who reported on 30 or more cases, were all experienced and, possessing our confidence in their ability, have been considered individually in Tables III and IV. The remaining 208, the great majority of whom were equally competent, are treated as a group, the number of cases examined by each of them being less than thirty.

The foregoing table (III) shows very definitely that there are marked differences in the length of the fourth phase, even by examiners of about equal ability in blood pressure estimation. The frequency, for instance, with which the length of the fourth phase was reported as 2-6 mm. varied from 43 per cent. to 99 per cent. of cases examined by each, and for the phase over 10 mm. from 0 per cent. to 20 per cent. It was found over 10 mm. by three examiners in 3 or 0.6 per cent. of 508 cases. This percentage is so small, where large experience is a factor, that it will give us little trouble. We think it extremely doubtful that the 291 cases reported on by the remaining eight examiners had a fourth phase over 10 mm. in 15 of this number (5 per cent.). The difference cannot well be due to such marked differences between the two groups, but rather to difference in interpretation. We recognize, of course, that the high percentage (5) above shown is not altogether comparable with the percentage (0.6) as there is much greater opportunity for variation among eight than among three examiners. None of the three, however, found the phase over 14 mm., as shown by Table IV.

TABLE IV.

LENGTH OF PHASE OVER 10 MM. BY EXAMINERS.

Examiner	11-12	13-14	15-16	17-18	19-20	21-22	23-24	25-29	30 & Over	Total	
A	..	..	1	2	..	..	..	..	..	3	...

Combined.	4	5	4	2	0	1	0	0	2	18	2.3%
All Others.	28	15	13	4	8	2	3	2	5	80	7.7%
All Combined	32	20	17	6	8	3	3	2	7	98	5.3%

One most excellent examiner, D, is shown by this table to have recorded a pulse pressure of over 30 mm. in two cases (5.4 per cent.) out of 37. We have not the slightest doubt as to the correctness of these readings and believe they serve to emphasize the fact that occasionally we meet with a very much lengthened fourth phase. In the 799 cases received from the eleven examiners it was reported over 18 mm. in 3 (0.4 per cent.) cases and in 20 (2 per cent.) of the 1,036 from other examiners, seeming to confirm the statement above as to difference in interpretation.

These differences are still better shown by Table V, which compares with the lengths of phases reported by all those reported by the eleven examiners. The number of cases with the phase over 10 mm. is for all examiners 98 (5.3 per cent.) for the eleven 18 (2.3 per cent.). When securing the data for this table the number of examiners reporting the phase 7-8 mm. was, for some reason not known, overlooked. The percentages given for the examiners are for those reporting a certain length of phase. As there is duplication the exact number who reported the phase over 6 mm. cannot be determined from the figures shown.

TABLE V.

FOURTH PHASE OVER 6 MM. BY EXAMINERS AND CASES.

Phase	All Examiners.				Selected Examiners (11)			
	Examiners	%	Cases	%	Examiners	%	Cases	%
7-8 mm.	..	..	197	10.7	10	90.9	70	8.9
9-10 "	51	23.3	165	7.0	9	81.8	46	5.8
11-12 "	19	8.7	32	1.7	3	27.2	4	0.5
13-14 "	17	7.8	20	1.1	3	27.2	5	0.6
15-16 "	15	6.8	17	0.9	4	36.3	4	0.5
17-18 "	5	2.3	6	0.3	1	9.0	2	0.3
19-20 "	8	3.7	8	0.4	0	0.0	0	..
21-22 "	3	1.4	3	0.2	1	9.0	1	0.1
23-24 "	3	1.4	3	0.2	0	0.0	0	..
25-26 "	1	0.5	1	0.1	0	0.0	0	..
Over 26	5	2.3	6	0.4	1	9.0	2	0.3
Total	..	..	460	25.1	..		131	16.8

There were 46 cases (2.5 per cent.) in which the phase was 15 mm. or over—Table VI, and 15 cases

TABLE VI.

FOURTH PHASE 15 MM. OR OVER BY AGE AND PULSE PRESSURE.

Age.	Cases	Systolic.	Diastolic				4th Ph.
			4th Pt.	P.P.	5th Pt.	P.P.	
20-24	2	129	98	31	78	51	20
25-29	5	129	99	30	80	49	19
30-34	9	127	100	27	79	48	21
35-39	10	127	95	32	73	54	22
40-44	9	130	104	26	83	47	21
45-49	5	130	95	35	75	55	20
50-54	3	134	102	32	80	54	22
55-59	3	129	97	32	71	58	26
All Ages	46	129	99	30	78	51	21

(0.8 per cent.) with the phase 20 mm. or over—Table VII. Only 14 of the 15 are shown in this table.

TABLE VII.

FOURTEEN CASES WITH THE FOURTH PHASE OVER 20 MM.

Age	Systolic	Diastolic				4th Phase
		4th Point	P.P.	5th Point	P.P.	
38	125	85	40	45	80	40
57	146	95	51	51	95	44
24	139	100	39	76	63	24
47	130	112	18	88	42	24
40	130	100	30	78	52	22
40	135	110	25	75	60	35
34	118	112	6	68	50	44
42	130	100	30	70	60	30
36	125	100	25	70	55	30
37	128	103	25	75	53	28
37	130	82	48	56	74	26
50	130	105	25	70	60	35
32	126	110	16	86	40	24
33	135	100	35	78	57	22
Combined	130	101	29	70	60	31

Comparing Table VI with Table II, we find the systolic in the former (VI) 4 mm. higher, the 4th point 11 mm. higher, and the 5th point 4 mm. lower than in the latter (II). The phase is here 15 mm. over the average 6 mm., 11 mm. of the 15 being due to higher 4th point and 4 mm. to lower 5th point. A similar comparison between Tables VII and II shows an increase of 5 mm. in the systolic with the 4th point 12 mm. higher and 5th point 12 mm. lower. The distinct increase in the average systolic in these two tables, 4 and 5 mm. respectively, is interesting. It is not uniform, however, by ages.

That the readings at the 4th in Tables VI and VII are correct is very doubtful. This is particularly well shown in Table VII where the average 4th point is 101 mm. and the average pulse pressure but 29. With the exception of three cases the 5th point (Table VII) is quite within normal limits. Were these three cases excluded the average of the readings at the 5th point would be 76 mm. These three cases, age considered, had normal 4th points and if not included would allow a higher average (105 mm.) at this point. They were the only three in the total number of cases with the 5th point under 60 mm.

It seems, then, that increased length of the 4th phase is more the result of reading the 4th point too high than the 5th point too low. Unquestionably one occasionally meets a case otherwise satisfactory with a very low 5th point, but the number is exceedingly small, being 3 or 0.16 per cent. in our cases. We believe, then, there is more difficulty in determining correctly the 4th than the 5th point and occasionally it cannot be heard. Age is not a factor, as shown by Tables II, VI, and VII. Experience seems important, as evidenced by Tables III and V.

Acuteness of hearing, or differences in ability to detect change in tone probably play a considerable part, for none of the examiners who reported the cases used in this analysis have impaired hearing, so far as is known.

Whatever the cause or causes, we think it evident that they do not affect interpretation of the 5th as much as the 4th point, and that, as shown by Dr. Jaquith, the 5th is the more desirable one to use, at least for insurance or general clinical examination. Referring to Table II, we find the average difference between the two points is but 6 mm. and from Table IV that at the worst but 7.7 per cent. show the 4th phase over 10 mm., at the best 2.3 per cent. with an average of 5 per cent. It was 2-6 mm. in 75 per cent.

Before closing we wish to state what appear to us well established and safe guides in selecting risks.

Ages.	Systolic.		Diastolic.	
	High.	Low.	High.	Low.
15-19	130-135	95-100	80- 85	60-65
60 and over	150-155	110-115	95-100	65-75

These we advance as guides and not arbitrary limits. We would not be willing, however, to accept risks at any age over twenty years with constant systolic pressures under 100 at the younger or over 155 mm. at the older ages nor with constant diastolic under 60 at the younger or over 100 mm. at the older ages.

These limits, it is felt, give ample allowance for all normal variations, the result of influences to which reference has previously been made.

Pregnancy Following Radiotherapy of Fibroid Uterus.—That radiation for fibroid believed to act through suppression of ovarian function does not necessarily entail sterility is shown by Delbet's announcement that pregnancy has followed three cases in the practice of Dr. Ménard. This throws doubt on the supposition that improvement of fibroids is due to the action of the rays on the ovaries. By localizing the action of the rays on the uterus the good possibilities will be realized without prejudice to the ovaries.—*Le Bulletin Médical.*

PRELIMINARY REPORT ON A NEW METHOD FOR THE CLINICAL DIAGNOSIS OF TOXIC THYROID STATES.

By WILLIAM N. BERKELEY, A.B., B.Ph., M.D.,
NEW YORK.
ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY.
WITH A NOTE ON THE SEROLOGICAL TECHNIQUE.
By JOHN KOOPMAN, B.S.,
NEW YORK.
SEROLOGIST TO THE NEW YORK DEPARTMENT OF HEALTH.

A SCIENTIFICALLY exact method for the diagnosis of plus, minus, and toxic thyroid states would be a great boon to clinical medicine. And the problem is not insoluble; but the solutions so far suggested are inadequate.

E. C Kendall[1] among others has proposed the basal metabolism as a guide to the existence of hypo- and hyperthyroid conditions. But apart from the expense and complicated procedure of this method is the objection that no one yet knows how many other clinical conditions may temporarily influence the basal metabolism in both plus and minus directions.

E. Goetsch[2] has suggested the severity of the patient's reaction to a measured hypodermic dose of adrenalin as a measure of his thyroid activtiy. I cannot learn that this test has proved generally popular or generally confirmatory of evident clinical signs. M. S. Woodbury[3] in a study of some fifty recent cases of thyroid disease at Clifton Springs, N. Y., concludes that the adrenalin test is an indicator of "general sympathetic hypersensitiveness" which may or may not be of thyroid origin.

It was my idea at one time that if the thyroid secretion appears in the blood in protein form, it might be picked up by a complement fixation test and titrated. In order to try out this supposition the following experiment was repeated a number of times: A healthy young sheep was immunized by successive injections of a saline suspension of thyroids from freshly killed dogs. Using the injection as antigen, a pronounced and abundant antibody could be demonstrated in the sheep serum in the course of a few injections. But not the slightest binding could ever be observed with normal dog serum as antigen. This seems to prove either that the thyroid secretion is not present in the serum at all in protein form, or that, if so, it is in too minute amount to be available for a fixation test. As I have not found any mention in the literature of such an experiment as this, it seems worth while to record it even in its present fragmentary form.

Failing in this attempt my attention was turned to the possibility that when the chemistry of the thyroid gland is materially disturbed, as in exophthalmic goiter, the thyroid toxins (assuming for the time that such bodies exist) might be accessible to study by the same (complement fixation) method.

There is almost no literature on this subject that I have been able to find, except some pioneer work done almost ten years ago by Prof. Marinesco, and his associate, A. Papazolu[4]. The latter of these observers claims to have found antibodies a number of times in the serum of patients suffering from Basedow's disease. He used as antigen aqueous, alcoholic, and ethereal extracts of Basedow goiters, parenchymatous goiters, and normal thyroids. Of his 38 tests 14 showed complete fixation, 12 almost complete fixation, and 12 were negative.

This work, while interesting and suggestive, dates back to the very early days of scientific serology, and seems not to have been very carefully controlled. Moreover Papazolu used alcoholic and ethereal as well as aqueous extracts of his thyroid antigens, thereby of course getting fixation with many luetic subjects.

Using non-lipoidal antigens (for method of preparation and serological technique see below) derived from various thyroid tumors (about ten in all) it has been impossible to get fixation with the serum of Graves's disease except in the case of a single goitre kindly given us by Dr. John Rogers. This growth Dr. Rogers thought to be a true Graves' tumor. Unfortunately it was all extracted, nothing being left for microscopic examination. Antigens from four normal human thyroids gotten at autopsy under favorable conditions entirely failed to bind.

About this time through a fortunate combination of circumstances Mr. Koopman observed that with *normal dog thyroid* random samples of Basedow serum would bind powerfully, and that they would not bind with any other dog organ.

Starting out with this test as a guide—*i.e.*, using dog thyroid as antigen—fixation experiments have been done on more than 175 human serums, of which 40 were under suspicion of positive thyroid dyscrasia.

Of the 40, 18 were clinically undoubted Graves' disease, 2 were probably so, 10 were doubtful, and 10 were probably *not* Graves. I have full notes of most of these cases; in all the instances where the blood only was sent (through the courtesy of medical friends kindly interested in the research), the diagnosis was made by a colleague in whom I had unusual confidence. I believe the chances of error in this regard are reasonably remote.

The 18 Graves' cases were all one plus to four plus. The probable cases were positive; six of the ten doubtful cases were positive; the ten "probably not" were all negative.

As to the controls, numbering over 135 patients, all were negative except one. This exception was a young married woman of about thirty years, with a tertiary specific skin lesion on one knee. She was not particularly nervous; her pulse was 96; her eyes and thyroid did not strike one as pathologically prominent. She had a positive Wassermann and a positive thyroid fixation. She was lost before it was possible to make any further investigation of her history and condition. All the other controls—representing nearly all the chronic, and many of the common acute diseases (non-infectious)—were, as already noted, negative. About 20 were old fibrocystic goitres. Serum kindly sent us by Dr. George Draper from a borderland case was, he reported, negative to the Goetsch test; we found it two plus positive to the dog thyroid test. Another serum (Dr. Jos. H. Fobes) was posi-

tive to the Goetsch test, and also two plus with dog thyroid.

The new test has been repeated hundreds of times and has been checked up with all needful controls. If anyone alleges that the binding is due merely to the chance appearance in human serum now and then of a native amboceptor, then he must also explain why in more than ninety-five per cent. of the cases the native amboceptor appeared in patients with a positive thyroid dyscrasia.

Speaking further for the value of the test is the fact that in several of the positive cases which have improved very much or apparently gotten well in the last eighteen months, the test has varied concomitantly with the clinical improvement, falling from four plus to two plus, and later disappearing entirely. Dr. H. H. Janeway, of the N. Y. Memorial Hospital, who has recently experimented extensively with radium in these cases, tells me that he considers the test of distinct value in the quantitative adjustment of such treatment to the clinical condition of the patient.

The number of cases so far observed is too small to make the suggestion more than tentative, but with this reservation I venture to hope that the new test may be found of value in several directions:

1. In the clinical diagnosis of a great many cases which are now very perplexing—early cases, late cases, borderland cases, anomalous cardiac neuroses, and thyroid tumors without definite signs of thyroid poisoning, such as unusual menstrual swellings, post-puberty enlargements, and fibrocystic goiters in the early stages. Such a test would help to differentiate exophthalmos due to other causes than Graves' disease, and would eliminate many cases of severe tobacco poisoning due to cigarettes, where the symptoms and signs (as recently noted in army soldiers and recruits) have been such as to deceive the very elect.

2. The test would aid in the adjustment of therapeutic measures to the immediate condition of the patient.

3. And finally it might throw considerable light upon the etiology of cellular tumors in general.

Subject to later modification the view may be suggested that spontaneous recovery in exophthalmic goitre is due directly to the formation of these corrective antibodies in the patient's own system; and that rest, careful feeding, and relief from anxiety contribute to the cure merely by aiding the patient's normal immunity-mechanism.

In explanation of so curious and unexpected a phenomenon I have no reasoned hypothesis. It may, however, be tentatively suggested, that dog thyroid contains a substance, or group of substances, native in the dog, but toxic in man. For such a supposition there are numerous analogies elsewhere in biochemical physiology. For this substance I offer the name *cynothyrotoxin* (of evident derivation), and I presume it to be formed in the human thyroid under the abnormal chemical conditions which appear when exophthalmic goitre develops. It is probably not the only toxin involved (as indicated above in the case of Dr. Rogers' specimen), but is of special importance, and is often present when plus thyroid states are abnormally excited.

In extenuation of the inadequate number of positive cases, herewith described, it may be said that however many cases I might publish, facts so unusual would still have to be verified by many other laboratory and bed-side workers. I have therefore concluded to "release" this report without further apology.

SEROLOGICAL TECHNIQUE.*

This reaction is apparently due to a specific thyroid substance which combines with an antibody in the blood of the patient.

The degree of specificity of the reaction depends of course upon the amount of thyroid antigenic substance in the antigen used. The antigen is an extract of the thyroid of normal dogs. It is best to use the mixed glands of five or six dogs. As at present prepared, the extract contains much extraneous matter which takes no part in the reaction; if some method of securing the antigenic substance free from all foreign matter could be devised, the specificity would be enhanced. As far as we have gone, we know that the antigen slowly deteriorates even when kept under the best conditions and after about three weeks it is necessary to obtain a new supply. Drying instantly spoils its antigenic properties and it does not withstand heating to 50° C. for 15 minutes.

The best method of preparing it which we have been able to find is as follows: The glands are obtained under aseptic precautions as soon as possible after the dogs have been killed. Each gland is trimmed carefully, and minced finely with sterile scissors. The whole mass is then ground in a mortar with a measured quantity of washed and sterilized sand and of dry sodium chloride. The amount of sand is of no importance, but the salt should be added in the proportion of 1/10 gram to each gram of gland used, and a few drops of 2 per cent. aqueous solution of tricresol are added for each ten grams of thyroid. This mixture is corked tightly and laid away in the ice-box. For use it is made up with distilled water, using 10 c.c. of water to one gram of the original amount of gland. The sand and solid matter are removed with the aid of a centrifuge.

The test is set up in form of a titration, using constant amounts of serum in not more than one-quarter of the least amount which is anticomplementary. The antigen is used in varied amounts, beginning with an excess and ending with the least amount which can be expected to give fixation. The exact amounts used will depend upon the total volume of the test the worker is accustomed to using. At the same time an antigen control is made with the same quantities of antigen as are put in the test. This procedure will obviate the necessity of putting in a separate titration of the antigen before the test itself is made. The result is indicated by the difference between the quantity of antigen which is anticomplementary of itself, and the quantity which binds complement in the presence of serum. A negative serum with the an-

*By John Koopman, B. S. The earlier part of this work was done in part at the Loomis Laboratory of Cornell Medical College. The assistance of the college authorities is herewith formally acknowledged.

tigen will often bind less complement than the antigen alone. A positive serum will bind with one-half or less than one-half the least anticomplementary dose of antigen. Fixation is carried out for from four to six hours in the ice-box. At the present time the range is short, but with improved methods of preparing the antigen it is hoped the range will become greater.

Besides the tests on human glands and human tumors (*i.e.* thyroid tumors), as above mentioned, we have not tried the glands of any other animals except bullock and pig. These were negative. It is quite possible that some may be found which will produce better results than dog thyroids.

Much more work also remains to be done on fixation results with extracts of true exophthalmic goiters. These are now very hard to get in New York operating rooms, as surgical removal of them has gone out of fashion; and when gotten we have not been able to devise any way of keeping them in fit condition for antigen formation for more than two or three weeks.

NEOPLASMS IN THE LIGHT OF EXPERIMENTAL STUDIES.*

By M. W. LYON, JR., M.D., Ph.D.,

SOUTH BEND, INDIANA.

Serious experimental work with neoplasms began with the first years of the present century. Previous to that time a few isolated inoculations had been performed. Following the work of Jensen of Denmark, in 1902, on animal neoplasms there began a series of painstaking observations on neoplastic growths from the experimental side. To-day in most medical centers are prominent workers on the cancer problem and there are maintained large collections of living tumors propagated in animals. This work has confirmed previous ideas regarding the cause and behavior of tumors as observed clinically besides yielding new conceptions of malignant disease. No work in medicine has been pursued more assiduously and yielded so little in the way of practical value so far as human beings are concerned. This paucity of results illustrates what a difficult one the cancer problem is.

The experimental side of malignant disease is essentially confined to its manifestations in the lower animals. In man the incidence of tumors in small, occurring neither in epidemics nor yielding an abundance of material that can be critically studied. The inoculation of neoplasms from one person to another, much less to a series of persons, cannot be done. The tumors most frequently studied experimentally are the sarcomas and carcinomas occurring spontaneously in the domestic varieties of rats and mice, and artificially propagated in other individuals of the same species. Spontaneous tumors have been observed in other domestic mammals, but owing to the larger size and greater commercial value of the animals such tumors have not been so carefuly investigated as those found in the smaller forms. A most interesting tumor has been found in the domestic fowl.

Once a malignant tumor has spontaneously developed in an animal it has usually been found possible to propagate it almost indefinitely by removing it from the original host and transplanting bits of it into many individuals of the same species as the original host. The transfer is made under aseptic precautions by inserting well under the skin a piece of the tumor about one millimeter in diameter by means of a hollow needle provided with a stylet. All individuals of the same species or race are not equally susceptible to tumor inoculation, nor are all tumors equally capable of growing in other hosts even of the same species. This is especially true of the first inoculations of the new tumor. With repeated inoculations the tumor may have its virulence increased so that the percentage of takes is nearly one hundred. Such work necessitates elaborate system of records showing the weekly progress of inoculated tumors. The propagation of new and established tumors is always done on a series of animals involving thousands of individuals.

When such a bit of tumor is inoculated from one host to another, there is transferred with it a small amount of supporting and vascular tissues of the original host. In a successful take, these normal structures of the old host are absorbed by the new host, while the tumor cells proliferate and attract into their mass connective and vascular tissue from the new host. Many tumors have been propagated long after the death of the original host. One of the Jensen mouse tumors is still under cultivation after nearly a score of years. Its original host has been dead many mouse generations.

The question arises as to whether these animal neoplasms are entirely in the same category as human tumors. Most of the mammalian tumors studied seem on the whole quite comparable to the sarcomas and adenocarcinomas of man. They occur spontaneously in animals of an age comparable to the cancer age of man although for purposes of experimental propagation young animals are almost exclusively used. Youthful tissues do not impede a neoplasm once it has started. These tumors sometimes attain a comparatively enormous size, often with a mass half that of their host or more. But they cause little inconvenience to their host, at least until necrosis has set in. The cancerous cachexia of man is not faithfully reproduced in these animals. The increased virulence of these tumors in repeated transplantations and their seeming immortality as carried on from year to year through a series of different hosts are features not seen in human tumors, but probably would be if the latter were subjected to similar treatment. Some of the animal tumors have a tendency to regress and to be absorbed. This natural disappearance should be kept in mind in all experiments having for their aim the artificial regression of tumors. Regression

*Read at 34th annual meeting St. Joseph Co. (Ind.) Medical Society, November, 1919.

or even complete disappearance of malignant growths in man has been noted.

One of the most remarkable of animal tumors is the chicken sarcoma of Rous (*J. Exper. Med.* xii, 696). It upsets many previous notions of neoplasms and even of biology. It was originally found in a Plymouth Rock hen and carefully transplanted to a series of chickens of the same strain. Its virulence was low at first, but with repeated transfers it became high, yielding nearly 100 per cent of takes. Subsequent work showed that the juice from this sarcoma after being passed through a moderate sized filter and entirely cell-free is capable of causing the development of another tumor when inoculated into another fowl. The same is true of the dried and powdered tumor tissue. Its vitality is destroyed by moderate heating (55° C.) and by antiseptics. (*J. Exper. Med.* xiii, 397). Whether this is a true tumor comparable to other sarcomas or is some unusual infectious process incited by a filter-passing virus is not quite clear. If the latter, it is difficult to see how this tumor is propagated in nature as it was only found spontaneously once. Two or three somewhat similar fowl tumors are known but they are not entirely like the original Rous chicken sarcoma.

The tumors most studied experimentally are essentially like those tumors of man which are beginning to be regarded as directly or indirectly due to chronic irritation, such as epitheliomas, carcinomas of the breast, uterus, and alimentary canal. Tumors which are obviously due to unbridled growth of embryonic rests, such as teratoid growths, or tumors like hypernephromas are not among those which have been experimentally studied, at least to any noteworthy extent.

The search for a specific parasitic cause of neoplasms has signally failed not only in the case of human tumors but also in that of the lower animals. The various bacteria that have been isolated appear to be accidental invaders of the neoplastic tissue. One remarkable retroperitoneal teratoid growth is recalled from which no cultures were made but which showed in many of the sections and without special stains very conspicuous large bacilli. No one could conceive that they had any part in causing the growth. The only reliable instance in which a bacterial organism has been shown capable of causing neoplastic growths is that of *Bacterium tumefaciens* of Smith (*Science*, n.s. lxiii, 871, 1916) causing tumor-like growths in plants, even growths of a teratoid nature. But the pathology of plants is quite different from that of animals. The search for protozoan organisms as causes of animal or human tumors has been equally unsuccessful. In this connection it must be remembered that in the case of the infectious granulomas there is found new production of tissue suggesting a neoplasm. There is also the very interesting case of Hodgkins' disease which is most tumor-like in its pathology. An infectious lymphosarcoma of dogs is also known.

Attempts to produce tumors in animals by mechanical means have been partially successful. The observation has been made that the parts of domestic animals subjected to constant irritation have developed malignant growths. Why all do not do so is as still unexplained as why all pipe smokers do not develop carcinoma. Some positive results have been obtained in the production of mouse adenocarcinoma (Marsh, *Jour. Cancer Res.*, ii, 427, 1917) by means of trauma and pressure. The trauma should be acute and discontinuous. Many attempts to produce epitheliomas in animals have usually resulted in causing no more than an obnormal proliferation of epithelium, even though substances such as paraffin and soot, supposed to be instrumental in the causation of some human epitheliomas, have been employed. When the irritation has been removed the epithelium has usually returned to the normal condition.

That a physical agent like the roentgen ray can excite tissue to develop into a malignant growth is shown by the unfortunate and unintentional experiments on man by the early workers with such rays. Sarcoma in the rat by roentgen ray irritation has also been reported.

The chemical substances that have been employed in an attempt to produce neoplasms experimentally are those which will dissolve fats or lipoids, or oily bodies themselves, or dyes soluble in fats or lipoids, such as Sudan III or Scharlach R. In the numerous attempts made by repeated injection of such substances into epithelial structures no true tumors have resulted. There are no records of their being inoculable from one animal to another. Certain tumor-like epithelial excrescences have resulted, but when the foreign substance has been removed or absorbed the excess production of epithelium has subsided. Recently Japanese investigators (Yamagiwa and Ichikawa, *Mitteil. med. Fak. Univ. Tokyo*, xix, 483, 1918) have caused the development of carcinoma by painting rabbits' ears with tar. A few of these tumors produced metastases.

Some of the most characteristic tumors that have been produced or discovered incident to experimental work are the well known gastric carcinomas of the rat, observed by Febiger, associated with the presence of the remains of a parasitic worm in them. This worm has for its intermediate host certain species of cockroaches. By feeding a series of rats on roaches infested with this worm, Febiger was able to see carcinomas develop in many of his animals. That they were true tumors is shown by their metastases in which remains of the worm do not occur. More recently others have observed the development of carcinomas in rats about the encysted stage of a tapeworm. Some of these tumors were successfully transplanted. The metazoan parasites in these cases can be considered to have acted only as physical and chemical irritants toward the production of epithelial proliferation.

From a series of careful observations of the action of an emulsion of cancer cells from animal tumors on the life of a protozoan organism, *Didinium nasutum*, *Calkins* (*J. Cancer Res.*, i, 205, 1916; ii, 399, 1917) has shown that such a cancer mush contains a stimulating and a lethal factor. Similar results were obtained when embryonic epithelium was substituted for the cancer cells, but not when adult epithelium was used. As irritants of epithelium cause a production of new and essentially embryonic epithelium, he conceives that by a proper adjustment of the lethal factor and the stimulating factor a vicious circle may be established, as a result of which an irritation and production of rap-

idly growing epithelium occur together with destruction of adjacent tissues.

The study of tumor statistics in man has not yielded positive conclusions as to the contagiousness of cancer, the existence of so-called cancer houses or communities, or as to the hereditary tendency of malignant disease. The study of tumors in animals on a large scale, and especially with animals which pass through many generations during the lifetime of a single observer, has shown an absence of anything like a contagious nature of neoplasms and an absence of anything corresponding to a cancerous house or community. On the other hand the observations of Maude Slye on an enormous number of carefully bred mice have shown a distinct hereditary tendency to malignant disease. This hereditary aspect involves a tendency for specific organs to develop malignant disease. From the rarity of gastric cancers found in mice and other animals the conclusion has been drawn that such cancer in man is associated with the heating of his food, the use of condiments, or some chemical change due to cooking. (*J. Cancer Res.*, ii, 401, 1917).

With respect to metastases experimental studies have shown that massage and manipulation of a tumor are potent factors in dislodging cells and starting them on their way to grow in distant parts. (Tyzzer, *J. Med. Res.*, xxiii, 309, 1913.) In a series of experiments involving over 600 rats Wood has lately shown (*J.A.M.A.*, lxxiii, 764, 1919) that the removal of small pieces of a malignant growth for preoperative diagnosis does not appreciably increase the liability to metastases. Metastasis depends mainly on the time the tumor has been growing in its host.

The experimental study of tumor immunity has yielded a few interesting results, but essentially none of practical importance in human therapy. As all animals including man are subject to a variety of chronic irritations, such as students of animal and human cancer have shown often result in malignant growths of certain types, the question as to why all are not victims of cancer remains to be explained. It can only be said that some individuals are naturally immune to malignant disease, whatever may be implied by the term naturally immune. That malignant disease is essentially one of animals past the prime of life has been demonstrated by human statistics and by observation on experimental animals. That young animals have no forces resistant against malignant disease is shown by the ease with which transplantable tumors may be inoculated into them. Natural immunity is well shown by those individual rats and mice in which successful takes fail to occur.

A more understandable form of immunity is that of species, although it is without an ultimate explanation. Mouse tumors are ordinarily not transferable into rats and vice versa. By special means a few cross species transfers have been made. A mouse tumor has been carried a short time in rats whose lymphocytes have been artificially diminished in number. A few workers have reported success in transplanting tumors in species distantly related to the original host. A few attempts have been made to transfer human tumors to anthropoid apes, but without success. If anthropoids could be obtained as readily as mice, and a large series used, perhaps some successful takes could be obtained.

The rôle of lymphocytes in producing tumor immunity has received considerable attention experimentally. In human pathology malignant growths are observed to be more or less surrounded of lymphocytes and related cells. It has been frequently noted that the zone of lymphocytes is more pronounced in less rapidly advancing neoplasms and essentially absent in the more rapidly advancing ones. Experimentally it has been shown (Murphy et al., *J. Exper. Med.*, xxii, 204, 1915.) that mice potentially immune to inoculable cancer develop a lymphocytosis after they have been inoculated with cancer grafts, and about grafts placed in immune animals there is a noticeable zone of lymphocytes. Potentially immune animals can be made susceptible to tumor grafts by a depletion of their lymphoid elements by appropriate doses of the roentgen ray or by benzol (Murphy et al., *J. Exp. Med.*, xxii, 1, 1919.) Smaller doses of roentgen ray cause a slight lymphocytic stimulation but not sufficient to render susceptible mice immune. (Murphy et al., *J. Exp. Med.*, xxii, 800, 1915.) Quite recently it has shown possible to produce a high grade of lymphocytosis in mice by subjecting them to a temperature of from 55° to 63° C. for 5 minutes. Such animals have a high degree of immunity against transplantable tumors and are also resistant to transplants which have been removed from them. (*J. Exp. Med.*, xxix, 25, 31, 1919.) The mechanism of lymphocytes in limiting tumor growth or in preventing succesful takes of experimental grafts is not clear and appears somewhat anomalous in view of the metastases that occur in lymph-nodes.

The tumor immunity in animals appears to be entirely cellular. Attempts to find in their serum immune bodies cytolytic for tumor cells has failed. Serum from potentially immune animals as well as from animals that have recovered from inoculation of tumor grafts has had no effect in immunizing or in lessening the growth of successfully implanted grafts when used prophylactically or therapeutically in experimental animals. In vitro tissue cultures of cancer cells can be as successfully made in the plasma of immune animals as in the plasma of susceptible animals.

Animals which have been successfully inoculated with tumors and in which the tumor has later undergone regression and disappeared are usually immune against subsequent inoculations of most tumors. Immunity against tumors has been produced in mice by inoculating them with skin from mouse embryos showing that an animal can be rendered immune against growth of foreign cells of various kinds. An analogous non-specific immunity exists in man in various infectious diseases, as children naturally immune against diphtheria have been shown to be more or less immune against other infectious diseases such as measles and poliomyelitis.

Two largely employed therapeutic agents have been subjected to interesting tests with animal tumors. Wood and Prime (*Ann. Surg.*, 1915, 751) report a series of experiments with the action of radium on mouse sarcoma and carcinoma. Varying quantities of beta and gamma rays together and gamma rays alone were used; alpha rays were not

used. One portion of the material used for the inoculations was subjected to the action of the rays and the other portion, untreated, was used as a control. Series of mice varying in number from 48 to 144 were employed in each of several experiments, being inoculated in duplicate with rayed and unrayed malignant tissue. These experiments showed a marked lack of ability of the rayed grafts to grow. In another set of experiments the tumors were rayed while in the animals, a part having previously been removed for a control. In this series the destructive action of the radium radiations was much less marked than in the series of experiments where the tissue was rayed in vitro. In many cases there was a marked delay in the development of the implanted grafts, sometimes no tumor being manifest in the inoculated mouse until after a lapse of five or six weeks while in the control mice tumors were evident at the end of a week or ten days. Later, Prime (*Jour. Cancer Res.*, ii, 107, 1917.) working with in vitro cultures of normal mammalian tissues and of mouse carcinoma, showed that radium produced a distinctly injurious effect on cell nuclei and prevented mitosis. No essential difference in its action on normal cells and on tumor cells was observable. Cancerous tissue is more susceptible to physical agents than normal tissue because of the rapidly dividing condition of its cells and its lack of a definite vascular supply.

Hill, Morton, and Witherbee (*J. Exp. Med.* xxix, 89, 1919) have recently carried on investigations regarding the effect of roentgen rays on transplantable tumors. The rays were applied in more powerful doses than can be applied therapeutically. The tumors were divided into two portions, one being rayed and the other used as a control. The effects of the radiations were somewhat injurious to the tumor cells but not markedly so. Starting with an original tumor growth, part being rayed and part not, they carried it through several generations, as many as fourteen in one series. The rayed generations of the tumor acquired a distinct immunity to the action of the roentgen rays and gradually grew to yield as high a percentage of takes as the unrayed control portions. Rays of low penetration appeared more harmful to the tumor cells than the more penetrating ones.

While the experimental study of malignant growths has not yielded the same valuable end results that have been obtained in other lines of experimental research in medical science, yet much valuable information has been obtained in regard to the etiology of tumors, their nature, some of the principles of immunity against them, and the action of certain physical agents on them. In view of the large number of animals of the same kind and in the same environment that can be studied with the same tumor, generalizations can be based on such results that in many ways are incomparably better than those drawn from a study of malignant disease occurring sporadically in human beings. It would be in the interest of conservatism and of the scientific spirit to test out by animal experimentation various theories and therapeutic measures with respect to neoplasms before drawing too generalized deductions in the case of human malignant disease.

122 North Lafayette Boulevard.

DENGUE: OBSERVATIONS ON A RECENT EPIDEMIC.*

By MOISE D. LEVY, M.D.,

Galveston, Texas.

Associate Professor Medicine and Clinical Pathology, University of Texas Medical Department.

DURING the latter part of the summer of 1918 (August to November) we had the opportunity of observing and studying in a limited way probably the most widespread epidemic of dengue fever that has visited these parts since the memorable epidemic of 1897. No definite record of the number of cases occurring is available, but an estimate by several physicians placed the number between 4,000 and 6,000, approximately one out of every six people being affected.

At irregular intervals Galveston has experienced mild epidemics of this infection. Osler mentions the epidemic of 1897, and Graves in 1908 reported a mild epidemic occurring here. It is seen by these recurring flare-ups that most likely mild cases are here at all times—because of the mildness either not being recognized, or the patients not seeking medical attention. The condition becomes noticeable only when it assumes epidemic characteristics. A confusing point in the epidemiology of this infection was the arrival in Galveston a short while before the disease appeared, of a number of United States marines from the West Indies, where dengue is known to be endemic. It is possible that these marines introduced the infection into Galveston.

Dengue is definitely one of the mosquito-borne diseases, and formerly the *Culex fatigans* was supposed to be the only variety responsible for its transmission. Recent work, however, tends to incriminate the *Stegomyia calopus*. Both of these varieties of mosquitos are present in Galveston in abundance during the summer months, and the presence of one or two cases of dengue as a focus could easily result in a widespread distribution of the infection.

While opinion is fairly uniform as to the mode of transmission of dengue, the question as to the etiological agent is still in dispute. Graham, as far back as 1903, stated that he found a protozoal organism in the blood of patients ill with dengue, which he considered responsible for the disease. His results, however, have never been confirmed by any of the many reliable investigators of this subject. The work of Ashburn and Craig has proved that the cause of this disease is a filterable virus. Recently McMullin has suggested that a poisonous protein is injected by the bite of a mosquito, and subsequently another mosquito biting the same individual injects more of the protein—an anaphylactic reaction resulting, which exhibits itself as dengue.

The recognition of dengue is comparatively easy when attention is called to the matter, but it may frequently be confused with other conditions, such as influenza. That such confusion did arise is evidenced by the reports filed with the Bureau of Vital Statistics in Austin, of numerous cases of dengue occurring in the northern portion of the State. Dengue is essentially a coastal disease, and that this

*From the Department of Internal Medicine, University of Texas Medical Department.

epidemic was confined to Galveston and its immediate vicinity seems to be borne out by the fact that very few cases came to the attention of the health officers in Houston, only 50 miles distant.

The clinical manifestations of the recent epidemic conformed in the greater degree to those noted in other epidemics. A noticeable feature, however, was the marked irregularity and variability of the symptoms in different cases. This point was impressed upon us by Assistant Surgeon General H. P. Carter, of the U. S. P. H. S., who was in Galveston during the height of the epidemic, and who saw several cases. To use his illustration, the dengue seen in Eastern countries is more or less regular and conforms in the majority of instances to one type, much like the staid and dependable Oriental, while in the Western Hemisphere the disease, in his experience, assumes the more erratic characteristics of the Occidental.

The onset in the cases observed by us was fairly abrupt, being ushered in with a sudden rise in temperature and headaches. The temperature was, with few exceptions, only moderately elevated, numbers of the students in the medical school not even being forced to stop attending classes. In others, however, the onset was rather stormy and was of the kind seen in an acute infection. The "saddle-back" temperature curve was observed in a large majority of the cases, but several showed a curve which was maintained two to three degrees above normal for several days. The marked predominance of the "saddle-back" curve is interesting when we consider Colonel McCullough's recent observations in this disease, wherein he doubts the appearance of the "saddle-back" curve of the temperature in most cases. The pulse was slow, as might be expected—the rate lagging much behind the proportionate increase to be expected with the elevated temperature. In no instance did we encounter the Faget type of pulse, a point also noted by Graves in his report of a previous epidemic. The pains complained of by patients were not so severe as one might be led to expect from some of the names given this infection. Eye pains, with associated headaches, were most frequent and most complained of, with the general body pains coming next. In not a single instance did we note the swollen joints mentioned by Osler—a similar finding being noted by Cleland, Bradley, and McDonald in their report of the 1916 Australian epidemic. The eye pains were extremely constant and frequently suggested the diagnosis. These pains were of a purely muscular nature, being caused by the movements of the eye ball, and were stated to be deep seated. The body pains were located chiefly in the lumbar regions, and to use the description of one of the students affected, felt as if an "elephant had walked across his back." Nervous symptoms were very prominent—chiefly exhibited as a marked depression, lassitude, irritability, or insomnia. In one case coming to our attention, well-marked hallucinatory symptoms were present. These hallucinations consisted of seeing and feeling a hand picking at the bed clothes and bed shirt; otherwise the case presented no symptoms out of the ordinary, and was not an especially severe infection, so far as the febrile reaction was concerned. The skin eruptions noted in the cases coming under our care were extremely varied—ranging from a large well-marked morbilliform type to a faint almost imperceptible scarlatiniform eruption. In most cases, where looked for, the preliminary rash or rather blushing of the skin was noted, and with the terminal rise of temperature the typical rash appeared. In several instances this rash was so much like that found in measles that Koplik spots were carefully looked for, but in the absence of these and other symptoms of measles a diagnosis of dengue was made.

A small proportion of our cases presented definite glandular enlargements, the inguinal, axillary and posterior cervical groups being involved in degree and sequence as given. These glands were only slightly painful. A great deal has been written on the blood picture in dengue, the characteristic changes being a more or less marked leucopenia with a reduction of the polymorphonuclear neutrophiles and eosinophiles and a relative increase of lymphocytes. In our perusal of the literature on the subject of dengue fever, the only mention made of any change in the erythrocytes was in a report by Bonne of a dengue-like fever in Dutch Guiana. In these cases the author found polychromatophilia with some basophilic degeneration of the red blood cells. McCullough states that he found no change in the red blood cells. In several cases which we have observed it was noted that, in addition to the usual leucopenia to be expected, there was a well-marked reduction of the red blood cells with a greater proportionate reduction of the hemoglobin, giving us a picture of secondary anemia. This change in the blood picture, it seems to us, might account for the marked lassitude and debility which is one of the most common of the after-results of dengue. In view of the fact that the toxin present in dengue must cause a depression of the function of the red bone marrow, as evidenced by the leucopenia, it seems logical to conclude that we would also observe a decreased formation of red blood cells.

As a rule, one attack of dengue is supposed to confer immunity, at least insofar as reinfection during the same epidemic is concerned. Instances, however, have been reported where repeated attacks have been noted during the same epidemic. We have observed several patients during this epidemic in whom reinfection undoubtedly occurred, as several weeks elapsed between the attacks. The symptoms in each attack were practically the same, although the pains in the second attack were of a milder nature. A rash reappeared during the second attack. That these were not relapses of the same attack is evidenced by the length of time intervening—three to six weeks.

The diagnosis of dengue is usually a simple matter, especially during an epidemic, although the differentiation from influenza, as in the recent epidemic of both diseases, frequently presents a very nice question. The absence of respiratory symptoms, the intermittent temperature, and the rash should serve to differentiate dengue from influenza. However, attention should be called to the fact that in some instances influenza may show a rash, which might be confused with that occurring in dengue. Scarlet fever is differentiated by the leucocytosis present; measles by the presence of Koplik spots, coryza,

and respiratory affection; acute rheumatic fever by the leucocytosis, acid sweating, and joint affection. At the present time yellow fever is not an infection which we are likely to see, but when present it may exhibit an extremely difficult question for differentiation. The jaundice, albuminuria, Faget type of pulse, and absence of marked blood changes should serve to mark a difference between yellow fever and dengue.

Our treatment of dengue has been entirely symptomatic. We have found that frequently, when aspirin and phenacetin would fail to relieve the body pains, large doses of sodium salicylate combined with sodium bicarbonate would meet with success. Occasionally small doses of heroin hydrochloride were necessary to relieve the pains. In view of the fact that dengue is definitely a mosquito-borne disease, efforts toward prevention by elimination of mosquitos would be more fruitful than trying to discover some remedy for the condition.

In the above presentation it has not been our intention to indite a complete symptomatology of dengue fever, but merely to call attention to some of the features of the recent epidemic which we have experienced. No mention was made of the gross pathology, as none of the patients have died.

In conclusion, attention is especially directed to the extreme variability of the symptoms presented and the entire absence of joint complications. The anemia, appearance of relapses of fairly frequent occurrence, and the not infrequent glandular enlargements are points which have not been stressed in reports of previous epidemics.

CASE OF INFLUENZA COMPLICATED WITH STREPTOCOCCIC BRONCHOPNEUMONIA, ENDOCARDITIS, ARTHRITIS, AND PYEMIA; WITH RECOVERY.

By JOSEF SEILIN, M.D.,
CHICAGO.
PATHOLOGIST, LAKE VIEW HOSPITAL.

THE several points of interest in this case coupled with the fact that arthritic and serious heart complications in influenza have been reported very rare are the reasons for this description. In the combined reports of the epidemic from 72 army hospitals in the United States, serious heart complications and arthritis are mentioned as being extremely rare.

S. L., girl, age 19, single, doing housework in her own home, became sick with influenza during the second flare-up of the epidemic in 1919-1920. She had had measles in childhood and had then remained well until progressive loss of weight and feeling of fatigue two years ago caused her to consult a physician, who probably diagnosed incipient pulmonary tuberculosis and had her sent to a tuberculosis sanitarium for treatment. She said she never coughed or raised any sputum and that she felt well after several weeks of sanitarium life, although she stayed at the institution for six months, being then discharged as cured.

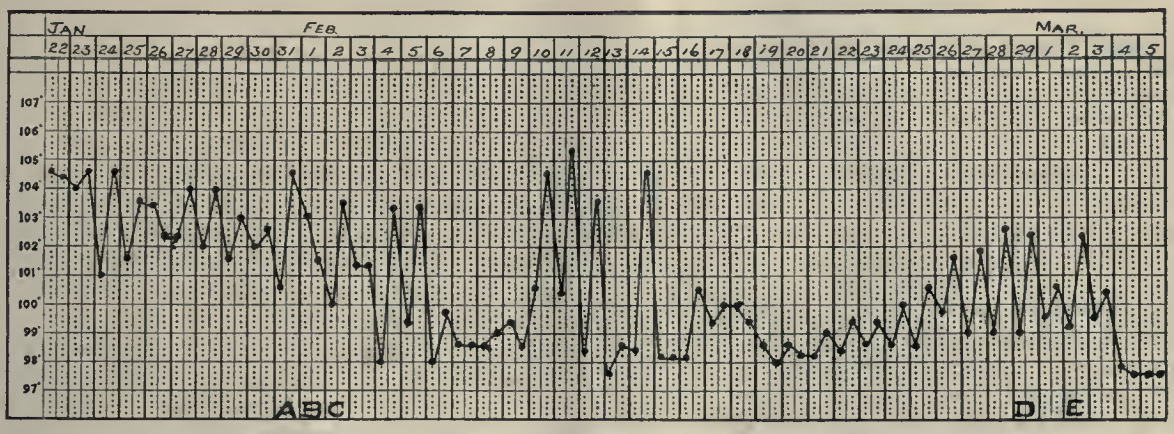
I saw the patient on January 20, 1920, the fourth day of her illness, and then the symptoms and physical findings were those of a violent, almost universal bronchopneumonia with pain and tenderness also beginning in the left shoulder. As the patient looked very sick and the lung findings were so extensive, hospital treatment was advised and decided upon. Upon entrance to the hospital the temperature was 104.8°, pulse 130, respiration 38. The facies was anxious, color cyanotic, eyes staring, lips dry and covered with dry dirty looking crusts, breathing labored and shallow. There was pain in the left shoulder and in the chest beneath the sternum, and in the sides on coughing. The cough was short and hacking and there was a scanty, tenacious, hemorrhagic sputum. Percussion showed areas of dulness varying in size scattered over both lungs with bronchial breathing over most of the chest and many coarse and fine crepitant râles on both late inspiration and expiration. The heart tones were clear and fairly strong. No murmurs were heard. The rest of the physical examination was negative. The blood showed a leucocytosis of 15,000. The urine had a trace of albumin, a few red blood cells and leucocytes, and also a few hyaline and granular casts. The sputum showed red blood cells, pus, streptococci, pneumococci, and staphyloocci.

The patient was treated by mustard plasters to chest and back twice daily, hot water bags to feet, liquid diet, tincture of digitalis 15 minims every four hours, heroine 1/12 grain when the cough became very troublesome, and sodium salicylate 5 grains every four hours. For the next seven days the patient's temperature varied from 101° to 104°, showing a fairly constant morning decline. The pulse came down to 100 and stayed around that point. There were also frequent attacks of perspiration preceded by chills of varying duration, from a few minutes to half an hour. During this time the chest findings became gradually more favorable and there was some diminution in the cough and expectoration. The left shoulder kept swelling and by January 31 was tense and very tender. There was also some swelling noticed around the region of the right shoulder about the 27th. Hot compresses were constantly applied to both shoulders. On January 31 the temperature suddenly climbed to 104.6°, the pulse became almost imperceptible, and the patient appeared to be dying. She was given hypodermoclysis of 500 c.c. of physiological salt solution containing 30 minims of adrenalin solution and this seemed to cause marked improvement. The following morning, after consultation, I opened the left shoulder joint and evacuated about a pint of green pus which showed the presence of *Streptococcus viridans* in pure culture. Two cigarette drains were left in the shoulder joint and the wound was subsequently dressed daily until healing took place. After this drainage was established the temperature dropped to 100° but started to go up again the next day. The right subdeltoid bursa was then opened and found to contain about 60 c.c. of the same kind of pus with the same organism. Following this there were three days of septic temperature with falls below normal on two days, then the temperature remained normal for three days and the patient appeared so much better that it was believed that convalescence had set in. However, on February 9 the cough suddenly became worse, precordial pain

was complained of and the temperature again for five days took on the septic curve, at one time rising to 105.4°. It should be stated that on the day the first shoulder was opened a cardiac systolic murmur appeared. It was rough and sharp and could be heard over the whole cardiac area, being loudest over the apex and in the fourth interspace to the left of the sternum. After five days of chills, septic temperature curve, and sweats the patient started to improve and the temperature would go down to normal and rise to 99° or 99.8° in the afternoons.

nausea and vomiting. For the troublesome cough 1/12-grain heroin tablets were administered very carefully and judiciously. The one time when the patient was apparently in collapse the hypodermoclysis of physiological salt solution with adrenalin seemed to tide her over. All the operating was done under local anesthesia with 2 per cent. procaine and adrenalin.

1307 N. Crawford Avenue.



A, Hypodermoclysis of 500 c.c. saline solution containing 30 minims of 1-100 adrenalin solution.
B, Left shoulder joint opened and drained.
C, Right subdeltoid bursa opened and drained.
D, Left subdeltoid bursa opened and drained.
E, Abscess in sacral region opened and drained.

A glance at the chart will show the interesting fact that here it commenced to rise a little higher every day like in typhoid, dropping to about 99° in the mornings. While this gradual ascent was being accomplished, the left shoulder was swelling again and a large hard mass, the size of a grape fruit, was forming in the sacral region beneath the gluteal muscles. On February 29 the left subdeltoid bursa was opened and drained, the old incision into the joint having been closed for some time and remaining so. This new accumulation of pus was confined to the subdeltoid bursa and seemed to be not connected with the joint cavity. On March 2 the sacral abscess was opened and an astonishing amount of pus was evacuated. All the pus was of the same bright green color and contained the *Streptococcus viridans* in pure culture. After this the patient's temperature rapidly dropped to normal and remained so. During this time the chest had cleared up remarkably. There were no dull areas to be found, no bronchial breathing, and only a few crepitant râles in the left infrascapular region. The cardiac murmur was very faint and a few days later could not be detected at all. The general condition improved rapidly, all the wounds healed up, and the patient now appears to be on the road to health.

In the course of this case there appears a point in the chart from Feb. 6 to 9 when the temperature was normal. To aid recuperation I had prepared an autogenous vaccine and on Feb. 9 I administered a small dose, 200 million killed bacteria subcutaneously. The reaction appeared severe, the temperature promptly jumping to 104.6° although it promptly dropped again to 100.4°. The next day I administered 300 million of the vaccine and this apparently provoked a rise to 105.2° with nausea, vomiting, and aggravation of all symptoms. So after that the vaccine was abandoned. The main reliance in this case was placed on careful nursing, plenty of nourishment in liquid and easily assimilable, form, plenty of water, alkali in the form of sodium bicarbonate, small doses of sodium salicylate, and the steady administration of digitalis, stopped only several times to wait for the subsidence of

Medicolegal Notes.

Opinion Evidence as Against Positive Testimony.—In an action for malpractice it was insisted by the plaintiff that the defendant in performing a mastoid operation severed the seventh or facial nerve, which was unnecessary, in consequence of which the plaintiff sustained damages. The trial court directed a verdict for the defendant. On appeal, the question involved turned on whether there was evidence sufficient to carry the case to the jury. It was contended by the defendant that there was no evidence that the nerve was severed; hence a verdict was properly directed. Paralysis of the face was shown, and there was evidence that severance of the nerve would cause that condition. But the evidence also showed that the paralysis might well follow an operation skilfully and properly performed from various other causes. It was shown by the evidence that the paralysis might have been caused by a "dehiscence," or by bandaging after the operation, or by cold drafts, and possibly other causes. Although it appeared that after the operation one side of the plaintiff's face was paralyzed, it was held that in order to warrant the trial court in submitting the case to the jury there must be some evidence that the defendant severed the facial nerve; and the appellate court found none in the record. There was positive evidence, not only by the defendant, but by Dr. B., a Chicago specialist, that the nerve was not severed. Dr. B. opened up the old scar in an effort to relieve pressure on the nerve, and testified that it had not been severed. Claim was made by the plaintiff's counsel that Dr. B. admitted the nerve was severed. The evidence did not support this contention. The claim was based on evidence of one Mrs. H., but her evidence as to what Dr. B. said when he was not under oath was not competent, except as laying a foundation for impeachment. Moreover, Mrs. H. admitted on cross-examination that Dr. B. might have said that the nerve was injured, but not severed. Some reliance was placed on the opinion of another physician. But it was held that his opinion could not raise a conflict with the positive undisputed evidence that the nerve was not severed, and that other causes existed for the paralysis. Proof of bad result raised no presumption of negligence in this case. Judgment for the defendant was therefore affirmed.—Finke v. Hess, Wisconsin Supreme Court, 174 N. E. 466.

THE VALUE OF CYSTOSCOPY IN CANCER OF THE UTERUS.

THE presence of certain lesions of the bladder observed in cystoscopy may confirm the suspicion of the cancerous nature of the lesion in the cervix uteri, but the only really specific vesical lesions resulting from uterine cancer are the little areas of cancerous granulations and carcinomatous nodules, deep ulcerative processes and vegetations the neoplastic characters of which have been identified. As to other lesions which have been thought to be a consequence of uterine cancer, they have been met with in numerous non-malignant affections of the uterus and adnexa reacting on the bladder, and also in certain varieties of cystitis. In the first phase there is a simple pushing back of the uterine growth causing an intravesical eminence. This is due to the tumor itself when it is large or to a serous collection in its neighborhood, which is an exceptional condition, although an undoubted instance has been reported by Violet and Murard. But simple retroversion of the uterus, fibroma of the cervix, or fibrous uterine polypi projecting into the cervix have been known to give rise to similar deformity of the floor of the bladder. A salpingitis prolapsed in Douglas' cul-de-sac may give rise to an elevation of the trigonum and projecting ureteral orifices. Retroversion is of special interest, because it frequently complicates cancer of the cervix, yet one must not be too hasty in attributing to cancer a marked projection of the floor of the bladder which, in reality, is a consequence of retroversion.

Deviations of the vesical floor, diverticula of the bladder, and folds of the mucosa are often due to a salpingitis adherent to the urinary reservoir. A pronounced diverticulum was seen by Cruet in a case of salpingitis which had formerly been connected with the rectum by a sinus. Finally, once the invasion is established, the mucosa becomes deformed, but at the onset it is respected. The neoplasm infiltrates the muscle and submucosa; there is a diffuse edema, or the mucosa lies in large folds, or bullæ form. All observers have regarded this edema as very important, and still it is not pathognomonic in any of its forms. Bullous edema has been met with in a case of a large pyosalpinx adherent to the bladder, and it is also present in inflammatory processes of the adnexa, in cases of uterine fibroids wedged in the pelvis, and in certain forms of cystitis. Bumm has described a bullous edema of the anterior vesical wall in a case of prevesical abscess following labor, which disappeared with the retrogression of the abscess. The same edema was seen by Cruet in a case of fibroma in a retroverted uterus, and in a case of antiversion there was edema of the vesical neck and trigonum. Bierhoff has seen bullous edema not only in cancer of the cervix uteri, but also in suppurating salpingitis adherent to the bladder; also in prolapsus uteri, simple and gonorrheal cystitis, ureteritis, simple ulcer of the bladder from a burn, and in cancer of the bladder itself. What is common to all these affections is the seat of the edema in the bladder; on a lateral wall in pyosalpinx; on the margins of the ulceration or around the neoplastic nodule in ulceration or vesical cancer; in the cases of urethritis and cystitis it is at the orifice of the neck of the bladder and apex of the trigonum that the maximum of edema is seen. Bullous edema has not exactly the same transparency in these affections as in uterine cancer; the bullæ are pinker and more opaque, while in the neoplasm the bullæ are whitish opaline elevations distinctly seen against a reddish background.

It is evident that in the majority of cases cystoscopy is unable to affirm the neoplastic nature of the involvement of the vesical walls, but in practice the question may be put differently. The diagnosis of carcinoma of the cervix uteri has been made by vaginal and genital examination which should always be done before cystoscopy. What we ask of cystoscopy is a diagnosis of the state of the vesical wall in order to ascertain if the neoplasm has extended to the bladder. Here a positive answer may be had. The retractions and circulatory disturbances indicate that the vessels of such a bladder pass through a mass of indurated and retractile tissue. The lesions seen by cystoscopy are not specific; it is impossible to estimate exactly how much simple mechanical compression, neoplastic infiltration, or inflammation is in play, because the adhesions and induration may be composed of newformed tissue or may be the inflammatory tissue which always accompanies or precedes cancer in its extension. The cystoscopy reveals these processes in the bladder; they therefore exist and that is all the surgeon wants to know. It is not essential to know exactly if the bladder involvement is inflammatory or neoplastic. We know it does exist and this will modify the operative prognosis. For this reason alone, cystoscopy should always be resorted to in completing the diagnosis of uterine cancer.

THE INTERPRETATION OF EXPERIMENTAL AND CLINICAL DATA OF COMPLETE ARRHYTHMIA.

IF it be admitted that, in the mechanism of complete arrhythmia, the type of activity of the auricles plays no determined part, in the same way as irregularity of the ventricular rhythm, from the

simultaneous action of several supraventricular foci of excitation, the following facts can be readily understood which have been derived from experimental and clinical observation. Firstly, ventricular arrhythmia may be accompanied by either fibrillation or paresis or paralysis of the auricles. In either case, the irregular excitations arising in the auricular portion of the primary fasciculæ none the less extend to the ventricle by its intermediary. Secondly, during a succession of completely arrhythmic systoles some contractions of sinus origin may reappear singly or in series with a normal succession and coordination of ventricular or auricular systoles; or some contractions corresponding to a known type of extrasystolia may occur if the sinus or an ectopic focus has been momentarily able to control the action of other foci and to assume the exclusive direction of the cardiac rhythm, either for a single contraction or a more or less prolonged series of systoles. These are difficult to explain if it be admitted that there is effective action of fibrillation on the ventricles, because it would be difficult to understand the cessation and return, which are sometimes almost instantaneous.

In the mechanism of complete arrhythmia, the auriculoventricular fasciculus remains not merely the organ of generation, but also of selection and transmission to the ventricles of supraventricular excitations. When an obstacle is interposed on its track, its division or destructive lesions will retain their rôle of a more or less effective *barrage*, protecting the ventricles and completely isolating them from irregular auricular excitation. The ventricular arrhythmia will then either be moderate or replaced by a slow and regular automonous rhythm, the auricular orifices remaining in a state of fibrillation or of paralysis. The fasciculus will also form an obstacle to the effects of excitation or inhibition of the pneumogastric, as well as to the action of atropine, digitalis, etc.

It is understood that, by the simultaneous action and the interference of several foci of excitation of ventricular and not auricular origin, one may conceive the possibility of complete arrhythmia of ventricular origin which have been demonstrated by experiments only. It may be likewise conceived that, from the effect of such excitations, the ventricular myocardium—either from exhaustion or some other cause such as an interference of the extracardiac nervous system—may present dissociated and irregular contractions, analogous to auricular fibrillation, but having as a consequence sudden or rapid death on account of the paramount physiological part played by the ventricles. Finally, the experimental production of auricular fibrillation with complete arrhythmia produced by paralyzation of the right auricle, may also be explained, perhaps, by the fact that electrization will only determine the production of multiple foci of excitation in the auricle having for effect fibrillation of the auricles on the one hand and complete ventricular arrhythmia on the other.

Do cases of complete arrhythmia purely of sinus origin exist? In other words, are there cases in which the sinus gives rise to stimuli unequal in both strength and time instead of equal strength and given out at regular intervals? Such an action on the part of the sinus cannot be regarded as impossible, but the existence of a sinus arrhythmia can be affirmed only if the auricular contraction regularly precedes the ventricular systole. Cases of this description are well known, but do not respond to the definition of complete arrhythmia in the strict sense of the term, because, although the cardiac contractions occur at irregular intervals, their energy remains the same. It would therefore seem logical to regard this as a special form of arrhythmia and not as complete arrhythmia, such as many observers are inclined to do, a term which implies a disturbance of all the elements entering into cardiac contraction. As to the sinus varieties of arrhythmia with inefficient auricular contractions or auricular paralysis, their existence is admissible, but it is impossible to recognize them clinically or to differentiate them from complete arrhythmia.

VARIABILITY IN THE NON-PROTEIN NITROGENOUS CONSTITUENTS OF HUMAN BLOOD.

As the use of the chemical examination of the blood became more prevalent it was found that the various nitrogenous constituents exhibited a variation that was often quite marked, and in a more or less casual fashion many authors have indicated what appeared to them to be the normal limits within which these variations occurred. But very few investigators have presented the results of an investigation that could be considered complete so that a satisfactory study of these variations has not been made. Hammett has been studying this point especially for some time and has recently published (*Jour. Biol. Chem.*, 1920, xli, 599) his figures together with a number of very interesting conclusions which he has drawn from them. In examining blood from the same individual from week to week he found that, while the composition varied, the level of the concentrations of the various substances was individual in character. He further is inclined to think that the sum of the average deviations of the constituents for any given individual may be an index of the metabolic stability of that individual. But this latter theory is one that will need a great deal of investigation before it can be substantiated. Individuals will have to be observed under many different conditions of mental and physical activity before dependable conclusions may be drawn.

It is interesting to note that in a very general way these substances vary in the blood much as they do in the urine. The creatinine exhibits the greatest stability, as Folin long since noted, while the urea nitrogen and the rest nitrogen show the greatest variations. With diminishing amounts of total non-protein nitrogen the urea nitrogen de-

creases both absolutely and relatively when compared with the other constituents, and it appears to vary reciprocally with the rest nitrogen. The changes which are found with these two substances result in a relative stability of the total non-protein nitrogen. Hammett further found that there was no practical difference in the constitution of the blood taken before breakfast and that taken three and one-half hours after that meal. This point is of practical importance in the selection of a time to draw blood for chemical examination.

It is of importance to emphasize the extent of these variations, for the average physician is only too prone to accept certain figures as the normal and to consider relatively slight deviations from them as evidence of some pathological condition. If he can remember that the non-protein nitrogen may vary from 27.3 to 45.5 mg. per 100 c.c., and the urea nitrogen from 9.7 to 25.1 mg. per 100 c.c. without necessarily indicating anything abnormal, he will be better able to appreciate the significance of the figures reported to him. Naturally our ability to detect any change in the figures in a given case would be greatly increased if we could know what the normal figures for that person had been. Since this is rarely possible, we must content ourselves in demanding relatively great deviations from the normal before we insist upon the presence of a disease condition.

THE ROENTGEN RAY AND TUBERCULOSIS.

It has been rather definitely shown that the lymphatic tissues, spleen, lymph nodes, and bone marrow are the ones which suffer principally after exposure to the *x*-ray, and there is a certain amount of evidence that the lymphocytes are the cells which are most active in protecting the body against tuberculous infection. On these theories it is easy to conclude that the use of the *x*-ray in the presence of tuberculous infection is strongly contraindicated. Such a conclusion was supported by the work of Morton, who found that guinea pigs that had received intraperitoneal injections of urine containing tubercle bacilli succumbed to the disease in a much shorter time when they were exposed to massive doses of the *x*-ray shortly after the inoculation. Morton's work seemed to be in harmony with that of Murphy, who studied the effect of the *x*-ray upon the lymphocytes. But much evidence soon began to appear on the opposite side of the subject. Lewis and Margot found that white mice that had been subjected to splenectomy showed increased resistance to the development of tuberculosis after inoculation, and it has recently been announced that the roentgen ray offers a hopeful method of treatment of tuberculous adenitis. It has apparently been shown quite clearly that antibody formation is interfered with by exposure to these rays, for Hektoen's work in this direction has not been successfully controverted, but the subject is still in a chaotic condition.

Recently Weinberg has attempted to reproduce Morton's results. In this he has been unsuccessful and reports that exposure to the *x*-ray has but little effect upon guinea pigs that have been inoculated with the tubercle bacillus (*Archiv. Int. Med.*, 1920, xxv, 565). It is impossible to reconcile the findings of these two investigators and the question must be settled by further studies. Weinberg found the same systemic response to the *x*-ray as other students have seen. There was a consistent drop in the white cell count, the number of lymphocytes being especially reduced. On microscopic examination he found that in the roentgenized animals there were fewer polymorphonuclear leucocytes and lymphocytes in the blood vessels and there were very few lymphocytes in the outer zone of the tuberculous lesions. The problem is an exceedingly cessful in clearing up some of the obscurity which important one in its practical bearing upon therapy, and it is hoped that early investigation will be sucnow surrounds it.

African Sleeping Sickness.

In the present and in the future Africa will have more need of the outer world to assist in the development of her resources, and the outer world will have more need of her products. These changes will multiply the avenues of traffic by road, rail, and steamer, and will also greatly increase the possible number of victims of tropical diseases and their spread from the regions to which they have been confined. Of these plagues, sleeping sickness is among the most dangerous. For over a century it has been recognized as a specific affection, but attracted but scanty attention until 1901. The opening of the Uganda led to its introduction—probably by human carriers—from the Congo, and the mortality from it assumed vast proportions. It was found in 1903 that the carrier was a tsetse fly which lived only near water, and in 1907 the epidemic was checked by the removal of the natives from a two-mile zone bounding Lake Victoria. But although the attempt had been made to eliminate all human carriers of this infection, some flies remained infective. Either many natives had broken the cordon, or there was a non-human carrier. Experiments made by Sir David Bruce in 1910 with captive antelopes showed that these animals artificially infected by the fly could in turn give the trypanosomes to clean flies by which they were bitten. It had long before been shown that the wild game of Zululand formed a permanent reservoir of the trypanosomes of sleeping sickness, which were carried by the tsetse fly to domestic animals and thus a menace to human beings. Suddenly sleeping sickness began to appear in Nyasaland and Rhodesia, and there was a natural alarm lest the fate of Uganda should be theirs. The great authority of Sir David Bruce supported the opinion that wild game should be exterminated in all regions bordering on human habitation and trade routes. A committee was appointed to sift the evidence and offer recommendations. The report, published in 1914, shortly before the war, summed up the facts as they were known, made specific recommendations, and also suggested further research. The committee held that Uganda sleeping sickness and Nyasaland sleeping sickness were dis-

tinct infections, due to different trypanosomes, carried by different species of tsetse fly, and requiring different prophylactic measures. It appeared to be certain that man himself was the permanent reservoir of the Uganda disease, whereas in the case of the Nyasaland form competent authorities were at variance. In the five years of war there must have been many changes in the distribution of the fly and of the diseases. It would be of great value were a competent authority now to traverse the whole region from the West Coast, through Central Africa to Uganda and down by Nyasaland to Rhodesia, to collect the facts and arrange for the correlation of research and of prophylactic measures. It is possible that, although on the retired list, Sir David Bruce may be asked by the British Colonial Office to undertake this investigation, and no man could be found more competent in the matter.

The Pathology of Senile Angiomata.

When a senile angioma is completely developed it forms a small, well-limited lenticular mass of cavernous tissue, situated exactly over the subpapillary vascular stratum of the dermis. The ectatic vessels which compose it have a well-marked contour and are lined with flat endothelium. Their walls are composed of fibrous connective tissue deprived of muscular elements and very poor in elastic fibers. Only a small number of cell elements are found: fixed cells of the connective tissue and some large cells containing much granular protoplasm, usually offering the general shape of plasmatic cells whose granulations stain in the same way as mast cells. The walls are rather thin, the lumen generally fairly regular—sometimes perfectly circular—but more often irregular on account of the vascular entanglement. In specimens removed the vessels contain red blood corpuscles and white cells. The latter consist of polynuclears with some lymphocytes and may even outnumber the red cells, so that some vessels, usually of small caliber, seem to be stuffed with white cells. These may form in piles or cover the walls of the vessels, forming a cuff, in the center of which are the red corpuscles. This condition is due to the sluggish circulation in the angioma. The cavernous tissue forms a compact mass and well defined, separated from the epidermis by a thick layer of connective tissue, immediately surrounded on the sides and underneath by normal dermic tissue. The epidermis covering the angioma is unchanged, but the dermoepidermic limit is flattened; the papillæ above the little tumor have about completely disappeared, as well as the interpapillary epithelial prolongations. However, on the circumference of the growth long epidermic prolongations may be observed which make a framework around the tumor and dip under it. The circumference of the angiomatous mass is not always perfectly regular, as there is a certain lobulation formed by somewhat thicker fibrous septa which dip into its mass and come from either its margin or surface. Some ectatic vessels may be observed at the margin of the angioma. When very small the angioma is not so distinctly outlined nor is it so compact in structure. It is made up of some clusters of ectatic vessels situated in the subpapillary stratum, but they do not offer the distinct characters of cavernous tissue. Their development is as follows: A small group of dilated capillaries will be seen, immediately surrounded by a narrow zone of round cells, resembling leucocytes. These cells form tracts of one or several rows which, starting from the already ectatic capillaries, dip into the interstices of the fibrous tissue and appear to be the commencement of newly formed capillaries. The process of vascular neoformation is usually presented in limited areas. The angioma consequently appears to grow by small successive masses or glomerulæ, which corresponds with the finely lobulated aspect of the lesion observed clinically. It is to be especially remarked how the pathological process is confined to the vessels. The neighboring dermis and overlying epidermis show no morbid changes, they being purely and simply pushed aside by the vascular neoplasia.

Enemata of Bile in Constipation.

Bensaude and Vicente read a paper on this subject last November before the Société Médicale des Hôpitaux which is condensed in the *Journal de médecine et de chirurgie pratiques* for January 25, 1920, xci, 2. Of interest is the fact that the resource is very old, if not one of the oldest known in medicine, for 1300 years before Christ a mixture of beef bile and milk in the proportion of one-third bile to two-thirds milk, was used as an enema for constipation by the Egyptians. Bile by the mouth may be shown to accelerate greatly the food passage through the small intestine as a result of direct contact with the latter, but in the present case the bile only reaches the colon. The authors have made the following demonstration: the patient ingests a barium meal—200 gm. gelatinous baryta with food—and 8 hours later a liter of water containing 10 gm. of extract of bile is injected into the colon. At this moment the barium is shown to be in the cecum and ascending colon. In from 2 to 3 minutes the barium is seen to move and in another minute is traversing the transverse colon. By the fifth minute the patient is at stool by reason of the urge. In the experiment the subject selected is one suffering from habitual constipation. The substitution of simple warm water without bile addition used for control shows that the first contractions are delayed to 8 or 10 minutes and that the fecal mass does not move. By deep massage the mass is moved to the hepatic flexure but does not clear this beyond the middle of the transverse colon and the contractions set up by the water alone die out. Bile thus is able to excite the colon as well as the small intestine, even when greatly diluted with water. A single dose of 10 gm. of bile causes colicky contractions. The authors have used the remedy in a number of different ways and prefer a dry extract which dissolves freely in water. Half a liter is plenty of addition and the fluid is allowed to enter by gravity from a vessel at an elevation of 30 to 40 cm. The interval of latency as already shown is not over 5 minutes. Thus far there have been no cases of "enema habit" developed and the authors note that the intolerance, which so often results from a long continuance of the use of suppositories, is never caused by bile enemata.

Differentiation Between Influenza and Epidemic Encephalitis.

Fornos of Valencia has compiled 18 points of differentiation between these two maladies, his paper having been read before the Royal National Academy of Medicine in February last (*La Medicina Ibera*, April 24, xi, 129). Grippe begins brusquely, encephalitis slowly; grippe in epidemics is highly contagious, the other slightly if at all; the grippe patient is lucid at the outset the other is not clear-headed; the grippe subject has a tendency to bradycardia which is never seen in the encephalitic; the grippe patient is albuminuric and the other never is; the grippe subject suffers from a toxemia and in encephalitis there is no evidence of toxemia; grippe gives no immunity to encephalitis and the converse holds good; in uncomplicated grippe there is a prompt defervescence but in encephalitis the fever subsides gradually; the fever is much higher in influenza of moderate type, for in the other malady 38° C. (100.4° F.) is seldom passed; in grippe there are pronounced gastroenteric symptoms not seen in encephalitis; the characteristic tongue, throat, etc., of grippe are absent in encephalitis; in encephalitis there are characteristic eye symptoms never encountered in grippe; the bacteriological finds are quite different in the two maladies. The author continues the tabulation of differences but his method is hardly just, for the comparison should be made between epidemic encephalitis and grippal encephalopathy. Cases have been reported in which diagnosis between these two affections was most difficult.

Antigonococcic Vaccine Per Os.

Some years ago a New York physician shocked his colleagues by an article in the Medical Record recommending the administration of the patient's own pus by the buccal route in gonorrhea, this being an outgrowth of the use of autogenous vaccines. It would appear that the idea was not so new or outlandish as to escape the attention of others, for we read that in 1913 Lumière and Chevrotier began to experiment with the use of sterile cultures of gonococci given *per os*. In this case the vaccine was stock vaccine prepared from urethral discharges not necessarily from the patient's own pus. The Frenchman obtained the idea from the previous use of typhoid vaccine by the mouth. Results from the use of this vaccine were not reported until 1916. The discharge was at first aggravated but later the gonococci steadily diminished in the discharge until bacteriolysis was complete. The idea was next taken up by Jacob, who treated 49 cases in this manner and obtained satisfactory results in two-thirds of them. An Italian, Doctor Georgis, assistant to the chair of skin and venereal diseases in the University of Turin, has recently reported his results with this resource (*La Riforma Medica*, January 31, xxxvi, 5) in both male and female gonorrhea and claimed a good result in about a third of the cases treated. Dr. Duncan, the American author referred to above, recommends a filtrate of live cultures (pus) for hypodermic use, but by the mouth the pus is to be administered as such, shaken up in water or given on sugar or in other vehicles.

News of the Week.

Psychiatric Social Workers Wanted.—The United States Public Health Service has appealed to the American Red Cross to begin a national campaign for volunteers to be trained as psychiatric social workers among the 50,000 World War veterans suffering from nervous and mental diseases in Public Health Service hospitals. Nearly two hundred workers will be needed before fall to care for such cases. There are today only 150 such workers in the country, and it is obviously inexpedient to take them from their present tasks. In accordance with this request, the Red Cross seeks volunteers for these positions at salaries ranging from $1,500 to $2,100 a year, offering summer school courses, on a scholarship if necessary, to provide trained workers by fall.

Fund for University of Rochester.—George Eastman and the General Education Board have given the sum of $9,000,000 to the University of Rochester for the schools of medicine and dentistry. Of this amount pledged, the General Education Board gives $5,000,000 and Mr. Eastman $4,000,000. Mr. Eastman's other gifts to the University of Rochester include a $4,500,000 school of music, the only one of its kind in the world; the Eastman scientific laboratories, $500,000 to the endowment raised in 1913 and $100,000 to the $1,000,000 Victory fund.

Another General Hospital Discontinued.—It is announced that the Surgeon General of the Army has been directed to arrange to discontinue U. S. General Hospital No. 31, Carlisle, Pa., as a general hospital on June 30, 1920, and has been authorized to utilize for Medical Field School purposes the Carlisle Barracks Military Reservation, Pa., and the acreage adjacent thereto now occupied and controlled by the War Department by virtue of permit from the Secretary of the Interior, dated August 22, 1918, the school to be designated as "Field Service School, Medical Department, U. S. Army."

Trading in Drugs Light.—According to *Drug and Chemical Markets*, trading in crude drugs has been greatly restricted lately. Many manufacturers of heavy chemicals are curtailing production, it is said, in anticipation of declining prices.

International Medical Conference.—Dr. Simon Flexner, director of the Rockefeller Institute, will represent the United States at a conference of the world's leading medical scientists at Geneva, July 5, the first formal meeting of the Medical Advisory Board of the League of Red Cross Societies. Representatives from other countries who will attend the international conference in July are: Belgium, Professor Brodet; Denmark, Professor Madsen; France, Professor Roux, Professor Albert Calmette and Dr. Leon Bernard; Great Britain, General Lyle Cummins, Sir Walter Fletcher and Sir George Newman; Italy, Professor Bastianello and Dr. Castellani; Japan, Dr. Kinnostke Miura; South America, Dr. Chagas.

Sanitation in the Virgin Islands.—A statement by the chief municipal physician of St. Thomas and St. John, Virgin Islands, shows that the death rate for the first three months of 1920 is the lowest on record, being about one-half the death rates recorded for the English, French and Dutch West

Indian Islands, and four below the 1919 rate of the registration area in the United States. In addition, the birth rate is said to have exceeded the death rate by over 133 per cent., while infant mortality was 76.9—less than half the infant mortality recorded in the surrounding islands, and considerably below the rate in the States. Health and sanitary work is under the supervision of the American naval government of the possession. The American Red Cross, during the last two years, spent nearly $44,000 for the equipment of hospitals on the island. Funds for the administration of the island are limited, but in spite of this, in two years the general death rate has been lowered from 39.5 per 1,000 to 13.6, and the infant mortality from 251.7 to 76.9.

Tuberculosis in Albania.—A survey just completed by American Red Cross doctors in Albania shows that there are over 300,000 cases of tuberculosis in that country, 80 per cent. of the entire population being affected.

Physicians' Exchange.—At a recent meeting of the Sedgwick County (Kansas) Medical Society at Wichita it was voted to establish an exchange in which addresses of doctors are to be kept and through which physicians may be located at any time.

More Rockefeller Donations to Medical Education.—The following institutions are to benefit by appropriations aggregating $20,261,000, recently announced by the Trustees of the General Education Board and of the Rockefeller Foundation: Washington University Medical School, St. Louis, $1,250,000; Yale Medical School, $1,000,000; Harvard Medical School, $650,000; Johns Hopkins Medical School, $400,000; Dalhousie University Medical School, Halifax, N. S., $500,000; various universities of Southern States, $287,350; negro schools, $943,500; American Conference on Hospital Service, $15,000, and the National Committee for Mental Hygiene, $25,000.

Fifth Avenue Hospital Planned.—Plans have been filed for a new eleven-story fireproof hospital to be erected at a cost of three million dollars on the east side of Fifth Avenue between 105th and 106th streets. It is to be known as the Fifth Avenue Hospital, and is to replace the Hahnemann.

Brooklyn Hospital Drive.—A drive to raise one million dollars for the erection of a hospital has been inaugurated by the residents of the Bay Ridge, Borough Park, Bath Beach, Kensington, Mapleton, and Flatbush sections of Brooklyn. The proposed hospital will be known as the United Israel-Zion Hospital.

Major-General Gorgas Honored.—The insignia of Knight Commander of the Order of St. Michael and St. George were bestowed by King George upon Major-General William C. Gorgas during the latter's recent visit to Millbank Hospital, London. The honor was conferred in recognition of General Gorgas' services to Great Britain and the rest of the world. He is en route to the west coast of Africa, where he will conduct researches concerning yellow fever for the Rockefeller Foundation.

Dr. George De Schweinitz of Philadelphia was recently given the degree of Doctor of Letters by the Moravian College and Theological Seminary, Bethlehem, Pa.

Obituary Notes.—Dr. French Austin Smith of Mullins, S. C., died at Johns Hopkins Hospital May 13, at the age of forty-eight. He was graduated from the Medical College of the State of South Carolina in 1895.

Dr. A. F. GREEN died at his home in West Jefferson, Ohio, May 21, in his sixty-first year. He was graduated from Starling Medical College, Columbus, Ohio, in 1894.

Dr. WALTER S. HATFIELD of Cincinnati, Ohio, died May 25, at the age of sixty-six. He was graduated from Hahnemann Medical College and Hospital, Philadelphia, in 1882, practising in Covington, Ky., for twenty-five years and latterly in Cincinnati.

Dr. HARRY D. TODD, police surgeon of Akron, Ohio, died May 25, at the age of forty-four. He was graduated from the Eclectic Medical College, Cincinnati, in 1898.

Dr. THOMAS NORMAN PEARSON of Morrill, Me., died May 28 after a prolonged illness, at the age of fifty-five. He was graduated from the University of Vermont College of Medicine in 1893.

Dr. CLARENCE M. GODDING, for more than thirty years a practising physician of Providence, R. I., died May 28, in his sixty-third year. He was graduated from the Medical School of Harvard University in 1883. He was surgeon in the out-patient department of the Rhode Island Hospital, visiting physician and surgeon, Providence Lying-In Hospital, and attending physician Dexter Asylum.

Dr. H. J. MILLARD, veteran physician of North Adams, Mass., died May 31, at the age of eighty-four. He was graduated from the Berkshire Medical College, Pittsfield, Mass., in 1864. He served in the Civil War, and was a charter member of his Post of the G. A. R. He was a member of the North Berkshire Medical Association.

Dr. WILLIAM W. HICKS, who was a doctor of divinity as well as of medicine, died June 1, at Cambridge, Mass., at the age of eighty-three. He was the first Methodist minister to become a missionary to India, organizing the Methodist mission field in that country in 1860. Dr. Hicks took an active interest in Republican politics, and was widely known as a lecturer and author.

Dr. EDWARD H. CURRIER of Manchester, N. H., died June 1, at the age of seventy-three. He was graduated from Dartmouth Medical College School in 1881.

Dr. EDWARD D. MCGIVERIN of Jersey City, N. J., died June 7, while en route to Los Angeles, Cal., for his health. Dr. McGiverin, who was born in 1886, was graduated from University and Bellevue Medical College in 1909.

Dr. WILLIAM S. JONES, Superintendent of the Soldiers' Home in Vineland, N. J., and New Jersey State Medical Examiner of Institutions, died June 8, in his sixty-third year.

Dr. EDWARD HERMAN M. SELL of New York City died June 7, at the age of eighty-seven. Dr. Sell, who was graduated from Bellevue Medical College in 1866, was the last of the seven physicians who organized the American Academy of Medicine in 1876.

Dr. VIRGIL THOMPSON of New York City died June 8. He was graduated from the New York Homeopathic Medical College and Flower Hospital in 1862.

Correspondence.

THE AFTER CARE OF ADDICTS.

To the Editor of the Medical Record:

Sir: At the recent annual conference of the correction and charities organizations much disappointment and surprise were expressed that no discussion developed on a subject so vital to public interest as the after care of addicts, for there are in New York City at all times many physicians well qualified to discuss the subject. But perhaps it was best that no time was allowed for free discussion as personalities and pertinent facts could hardly have been avoided.

The newspaper reports probably would have included mention of one "lay-medical" institution and a so-called "normal cure." Information as to how addicts have been directed to such places and also might have been disclosed the real reason why the Board of Health closed its clinic for addicts.

The reading of a paper on the "After Care of Addicts" at the above referred to meeting was a plea for sympathy for addicts and a proposal for New York State to buy Lebanon Shaker farm for a colony of addicts. If the colony plan is the after care proposed there is nothing new or original about the scheme, for the Department of Correction has been running the Riker Island Municipal farm for years. Here real constructive work is being done for the addict, thousands being rehabilitated. They stay from three to six months and leave with from 30 to 50 lb. gain in weight and not 10 per cent. but 100 per cent. cured. They are cured unless they desire to return to their old companions.

Here, at this point of leaving the custodial care of any institution or farm colony, is the *great unsolved problem.* Those unfamiliar with the subject believe that compulsory registration and a regular examination, perhaps once a month, of every addict should be enforced for three years after leaving the custodial care. One can readily see what an opportunity is here presented on a large scale for medical profiteering. The Cotillo Bill recently presented at Albany forcing "all addicts to be sent to a sanitarium" was a brazen attempt, it is charged, on the part of certain interests to profiteer on these unfortunates.

The paper referred to stated that 200 out of 2,300 patients were cured of addiction, 90 per cent. being failures, and the cost to our city was $200 for each case. Anyone familiar with addicts must know that a short treatment, such as received at North Brother Island, is a joke so far as permanency goes. Not a day less than three months is necessary to reconstruct an addict, and farm life with good food and air under custodial care is a prime requisite.

My criticism of sanitariums and profiteering physicians I hope may provoke discussion and bring forth some clever and constructive ideas which are really new, and particularly which pertain to the after care. By after care is meant that given to the addict after leaving the custodial care of the farm, and the question what is *then* to become *of the patient?* This has been our great problem in the correction department of our city, and will continue to be until addiction is recognized as more of a disease than a habit, and until some form of follow up constructive moral treatment or supervision is carried out.

Edwin C. Chamberlin, M.D.,
Supervising and Visiting Physician, Department of Correction, New York City.
4 West Eighty-fourth Street, New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, May 21, 1920.

American Hospital in London.—Some months ago the plans for the establishment of an American Hospital in London were described in a London Letter in the Medical Record. It was then stated that the idea of such an institution originated in the brain of Mr. Philip Franklin, a nose and throat specialist of American birth residing in London. Sir Arbuthnot Lane, Sir John MacAlister, the late Sir William Osler, Sir John Bland Sutton, Sir Humphry Rolleston and many other well known members of the British medical profession, enthusiastically supported the movement. The plans are now considerably advanced. Ex-President Taft has accepted the offer of president in America; Lord Reading is president in England, with Lord Bryce as vice-president. American residents in London have formed themselves into a committee, which includes in its membership many prominent names, and steps are now being taken to incorporate the institution in conformity with the laws of the State of New York. It is hoped to open a temporary building for free patients before the end of the year. As previously pointed out, the hospital is intended to become the principal research center in Europe for American medical graduates, and later on a vigorously conducted campaign will be opened to raise a large endowment fund. The committee in the United States consists of Dr. George W. Crile (nominated by the American Academy of Science on International Relations), Dr. W. J. Mayo and Dr. Charles H. Mayo of Rochester, Minn., Dr. A. H. Ochsner of Chicago, Dr. Rudolph Matas of New Orleans, and Dr. Franklin Martin of Chicago. The British and American committees will work together. One of the most important aims of the establishment of the hospital is to act as a link in binding together the two nations for the advancement of medical science as affecting the welfare of humanity. It is also actually and primarily intended to serve as an important part of the scheme to render London the European post-graduate medical center for Americans. Before the war few American medical men cared to pursue their post-graduate studies in London because it was lacking in opportunities and facilities to do this with advantage. They betook themselves naturally to Berlin and Vienna where they found exceptionally good facilities for professional instruction and opportunities for social life. Since the end of the war, of course, conditions have changed and the leading members of the American colony and the leading members of the British medical profession in London have resolved that American graduates who come to this country

shall find in London the facilities they were formerly offered on the continent. Thus it may be asserted without exaggeration that the organization of the American Hospital bids fair to become of international value and importance while, at the same time, it possesses great possibilities for the advancement of science.

War Disability Pensions.—The Minister of Pensions has circulated recently the following statement of the rates of pension approved by the Government for present war cases, which term will include only: 1. Men discharged with disability during the war, and 2, men discharged after the war on account of disability recognized by the Ministry of Pensions under the war warrant as attributable or aggravated by service in the war. Basic rate of pension for men discharged during the war for disabilities not attributable to service: Navy, over 10 years of age, one shilling a day; over 14, one shilling and sixpence a day; over 16, one shilling and ninepence a day; over 18, two shillings a day; over 20, two shillings and sixpence a day. The daily rates set out above will be applicable in the case of the following classes of soldiers: 1. Re-engaged men; 2, men re-enlisted to complete a term of service which, with former service, makes a total of at least 21 years; and 3, men who have had the above periods of continuous service with the colors, although they may not have re-engaged. Scale of service allowance in addition to disablement pension in attributable or aggravated cases: The disability pension will be paid in full and in addition the following service allowance will be paid to those men who come within the above mentioned categories: Over 10 years of age, seven shillings a week; over 14, eight shillings a week; over 15, eight shillings a week; over 16 and up to 18, nine shillings a week; over 18 and up to 20, ten shillings a week; over 20, eleven shillings a week, and over 21, eleven shillings a week.

State and the Blind.—The Government bill to promote the welfare of blind persons, the text of which has just been issued, provides that every blind person who has attained the age of 50 shall be entitled to receive such pensions as, under the Old Age Pensions Acts, 1908 to 1919, he would be entitled to receive if he had reached the age of 70, that is, about fifteen shillings weekly. County and Borough Councils are authorized to provide and maintain or to contribute towards workshops, hotels, homes or other places for the reception of blind persons, and, with the approval of the Minister of Health, to make such further arrangements for promoting the welfare of blind persons as they may think fit. This section applies to the city of London. Subject to certain modifications, the War Charities Act, 1916, shall apply to charities for the blind as if it were re-enacted. The measure which applies to Scotland and Ireland and whose short title is the Blind Persons' Act, 1920, will, if passed, come into operation on June 4 next. The bill was introduced by Dr. Addison on April 26 last.

Progress of Housing.—The present position in England and Wales with regard to housing schemes may be summarized as follows: Housing schemes submitted to the Ministry of Health, 9,821; approved, 6,041. Area of sites in acres, submitted, 68,000; approved, 47,000. Replying to a letter a few days ago Dr. Addison said that the total amount required for housing purposes during the year was estimated at £120,000,000; but it was not possible to say how much of that sum must be raised by means of local housing bonds. So far as returns at present show, the sum raised for housing is about £15,000,000, of which £2,000,000 has been raised by local bonds.

Bequests by Sir William Osler to Oxford and McGill Universities.—Sir William Osler, regius professor of medicine in the University of Oxford since 1905, who died on December 29 last, left an estate of the gross value of £15,565 with net personality £11,650. The testator left his medical and scientific library to the medical faculty of McGill University, Montreal. All other property to his wife, but after her death or earlier if she should wish, he left his residence, 13 Norham-gardens, Oxford, to be given to the dean, canons and governing body of Christchurch, as the residence of the regius professor of medicine.

Scientific Inquiry to be Made With Respect to Shell Shock.—In the British House of Lords on April 28 last, a discussion of shell shock took place. Lord Southborough, after calling attention to the different types of hysteria and traumatic neurosis, commonly called shell shock, from which many soldiers suffered during the war and after referring to the death penalty inflicted upon men by courts-martial on the charge of "cowardice," moved that the Government make inquiry into the expert knowledge derived by the army medical authorities, and the medical profession with the object of recording for use in time to come the experience of the war, and to advise whether by military education or otherwise some scientific method of dealing with such cases could not be devised. He asked if it were not possible to prepare the minds of soldiers against the disasters of hysteria and neurosis. He pointed out that Dr. Morton Prince of Boston, Mass., had given great attention to the subject at home, at the base, and in the hospitals of France and England. He was of the opinion that it might be driven into a soldier's mind as part of his ordinary training that "shell shock" was a form of hysteria due to his own thoughts and fears, and external suggestion arising from the condition of the modern battlefield, and that as long as he received no physical injury there was little danger to be apprehended from the occurrence of shell shock. The speaker thought the efficiency of an army might well be impaired by shell fear, and it was worth while considering whether some method of giving confidence by training and education might not be devised by a committee. He therefore recommended the appointment of a committee. Lord Haldane, who took part in the discussion, remarked very aptly that it had too often been the custom because a man was a very eminent medical man, to ask him to investigate a branch of a very great science which had ramifications with which he was not familiar. In a matter of this kind they ought to get together a small body of picked men of the highest eminence in the particular branch of investigation. The Under Secre-

tary of War said as regards the request for an inquiry, the view of the Government was that great advantages might be obtained from such an investigation. Many of the nervous and mental conditions encountered were entirely new to many of the medical men concerned, and there had been a great many expressions in different medical journals of their individual views on the subject. It was thought that it would be of great value if these different views could be gathered together and thoroughly investigated by such a committee as had been suggested. The request for a governmental inquiry into shell shock was granted.

Post-Graduate Students and Practical Midwifery.—Medical post-graduates in London who wish to obtain experience in practical midwifery are notified in the Bulletin of the Fellowship of Medicine and Post Graduate Medical Association, May 8, 1920, that vacancies for maternity assistants will be available in the district of the London Hospital, Whitechapel Road, during the next four or five months. The appointments extend for one month, but it is probable that the hospital authorities may be able to consider an appointment for shorter or longer periods if desired. Maternity assistants are instructed in their work by the resident accoucheur, and are under his control during the time they are holding the appointment. During the tenure of the appointment they are provided with free board and residence. A fee of five guineas, or about $26, is charged for the course. Applications for further particulars may be made to the secretary of the London Hospital Medical College, Turner Street, Mile End, London, E. C. Attention is drawn to this notice because those who may be thinking of coming on have made up their minds to come to London for post-graduate instruction may like to know that there are extremely good facilities there for training in midwifery. The London Hospital, the largest hospital of Great Britain, is situated in the midst of the East End, the poorest and most thickly populated district of London. Probably there is no other district of the world where the opportunities for practical training in midwifery are so good.

Progress of Medical Science.

The Boston Medical and Surgical Journal.

June 3, 1920, clxxxii, 23.

1. The Clinical Importance of Anatomical Anomalies in Billary Surgery. Daniel N. Eisendrath.
2. Caesarean Section Under Local Anesthesia Combined with Morphine and Scopolamine Narcosis. Frederick C. Irving.
3. Some Surgical Aspects of Syphilis. William Pearce Coues.

1. The Clinical Importance of Anatomical Anomalies in Biliary Surgery.—Daniel N. Eisendrath presents an illustrated discussion of the various anomalies of the blood vessels and bile ducts, pointing out that the increase in the number of operations for the removal of the gall-bladder has been accompanied by the report of many accidents due to anomalies of the bile ducts and blood vessels of this region. The occurrence of such variations receives either no mention at all or only a brief one in nearly all standard works of anatomy and even in those of operative surgery. The anomalies discussed are presented under the following heads: 1. Variations in the relation of the right hepatic artery to the main hepatic duct. 2. Variations of the gastroduodenal artery. These are of especial importance in operations on the common duct but may also be of equal interest if the only cystic artery arises from the gastroduodenal, or if such an anomalous vessel constitutes one of two cystic arteries. 3. Anomalies in origin of a single cystic artery. 4. Relation of a single cystic artery to the main hepatic duct. This is of the utmost importance in cholecystectomy especially if the operator attempts to ligate the cystic artery close to the hepatic duct. If the vessel should retract behind the duct while bleeding, it is easy to see how a blind thrust of the blades of artery forceps could include the hepatic duct. 5. Two cystic arteries. 6. Variations in the course and mode of union of the cystic and hepatic ducts. 7. Variations in the hepatic ducts.

12. Gonorrheal Vaginitis in Children. Charles Wachs and Charles Mazer.

5. The Relation of Appendicitis to Intrapelvic Disease in Women.—Frank C. Hammond holds that appendicitis occurs with sufficient frequency in women to make it important to the gynecologist as well as to the practitioner. Clinical experience shows that the diagnostic problem is often a perplexing one, when it is necessary to differentiate between inflammation of the appendix and involvement of the internal organs of generation of the female. The diagnosis prior to puberty is comparatively easy. It is important to bear in mind that appendiceal and adnexal disease coexist in a great number of cases. Appendicitis in the female may be mistaken, among other conditions, for pyosalpinx, ovarian abscess, suppurating ovarian cyst, torsion of the pedicle in ovarian cyst, ectopic gestation, abortion, or even for dysmenorrhea. Those who have not had a large experience will find that what at first seemed to be a straightforward disease has become one of the most difficult and treacherous. The only means of distinguishing the different types of the disease is a large experience, and even then it is frequently difficult. A careful history should be taken of every patient. The right chest in every instance should be carefully studied. A bimanual or rectoabdominal examination should be made as part of the physical examination of every female patient beyond the age of puberty. At the time of operation, if an incision is made for the exposure of the appendix, irrespective of the physical condition of the appendix, the surgeon's finger should be passed down into the right pelvis to palpate the right adnexa.

12. Gonorrheal Vaginitis in Children.—Wachs and Mazer report the results of the use of Dakin's oil in a series of fifty-eight cases of chronic gonorrheal vaginitis in children. The preparation was of one per cent. strength, freshly prepared. The method employed is as follows: The child is placed in a partial Trendelenburg position, the vulva cleansed with boric acid solution, and the vagina filled with the oil, by means of a medicine dropper, the capacity of which is two drams. On withdrawing the dropper the labia are compressed for a few minutes, so that the vaginal mucous membrane is thoroughly bathed in the oil. The medicine dropper is boiled after each treatment and dried with ether. This treatment was administered every other day in the clinic, and the mother was in-

structed to do likewise on the days she did not come to the clinic. The patients treated thus, though somewhat irregular in attendance, showed marked improvement, both clinically and bacteriologically, within a month. Smears were taken regularly every two weeks. At the end of three months Wachs and Mazer were able to discontinue treatment in twenty-five cases with instructions to report for examination every other week. At the end of four months they had discharged thirty-nine patients, the remaining six patients, while much improved clinically, still showed pus cells and many bacteria on microscopic examination. In these cases they used one-quarter strength of the standard Dakin's solution in the form of douches in the clinic, with instructions to the mother to continue the oil at home.

3. Surgery of the Thyroid.—John F. Barnhill discusses this subject from the point of view of the relationship of laryngology to disease of the thyroid body. His operative experience is based on 150 cases. In more than ninety per cent. of the cases examined disease of the tonsils was clearly evident, and, judging them from the most modern point of view as to what constitutes a diseased tonsil, he thinks practically all might reasonably have been classed as having foci of infection in the tonsil. In more than fifty per cent. of his goiter cases in which operation was performed during this period, the tonsils were removed before the thyroidectomy, sometimes as long as a year previously, in the hope that the goiter operation might thus be avoided. It seems certainly true that after the thyroid is once diseased the removal of the tonsils has little appreciable beneficial effect on the thyroid disease. Indeed, he has seen the thyroid rapidly enlarge and the thyrotoxic symptoms increase after the performance of a most complete tonsillectomy. These observations, however, do not form a good argument against the possibility that the diseased tonsil may have been the original focus from which the thyroid received its infection. The frequent presence of infected tonsils in thyroid cases points almost certainly to a connection between the two diseases. He emphasized the point, however, that clinical experience seems to justify the belief that when the thyroid is once diseased, from whatever source, the removal of the tonsils has but little effect on the future course of the thyroid ailment, but does, of course, improve the physical condition of the patient, and that tonsillectomy is, therefore, to be recommended as a preoperative measure of great value.

4. A Clinical Study of Infections of the Hand.—H. W. L. Molesworth analyzes 168 cases of infections of the hand as seen in working men and women, from which he concludes that these infections are too frequently the cause of grave disability. The cases fall most naturally into the following groups: Group 1.—(1) Perionychia (infections around the nail); (2) abscess in the pulp of the finger; (3) abscess on the palmar aspect of the hand and fingers. These three constitute the most important primary infections. Group II.—(4) Suppurative tenosynovitis; (5) bone and joint infections; (6) fascial space abscess in palm and forearm. These constitute the most important grave secondary infections. Group III.—(7) Abscess on the dorsum of the hand and fingers; (8) "carbuncular infections"; (9) trivial infections (chiefly subcuticular abscess); (10) lymphangitis and glandular abscess; (11) cellulitis. The lesions in Group I, while remaining in that group, are relatively trivial; but they readily give rise to the Group II infections, which are responsible for nearly all cases of sever crippling. From this study Molesworth found that it was very unusual for a case to develop a severe infection if it had been first seen while it was in the Group I stage. Part of the blame must be attributed to the prevalent impression in the minds of the lay public—and it is to be feared in the minds of some members of the medical profession—that a "whitlow" is a suitable object for treatment with poultices, ink, ointment—in fact, anything but free drainage. The time to treat these conditions efficiently is in their early stages. When tendon sheaths, etc., have become infected the hope of a useful finger is a thing of the past; the object of treatment then becomes to save whole hands, forearms, and even lives. The outlook of the public and the profession towards hands is much the same as it was toward the appendix twenty years ago. If localized tenderness became the danger-signal in the hand, as it has become in the abdomen, and if suppuration in the hand, however small the area involved, were regarded as an indication for immediate operation, the morbidity of infected hands would fall in much the same way as the mortality of infected appendices has fallen.

2. On the Use of Polarized Light in the Detection of Suture Materials Embedded in the Tissues.—M. J. Stewart holds that many of the suture materials in common use by the surgeon are optically active, and that the polarizing microscope affords a ready means for their detection in the tissues as well as for their subsequent investigation. Since the optical activity of these substances is unaffected by treatment with the usual dehydrating and clearing agents, paraffin sections are all that is required for the demonstration of the phenomenon. If such a section be viewed microscopically between crossed Nicol's prisms, the particles of suture material present will, in certain instances, show up brilliantly illuminated on a dark background, and in this way they can often be picked out with great readiness, even when their presence has not been previously suspected. The material on which Stewart based this study consisted of twenty-six specimens containing suture relics. Most of them were from portions of tissue which had been excised during life by the surgeon; a few were obtained post mortem. Eighteen specimens were found to contain silkworm gut, five catgut, and six silk. The age of the various specimens, that is, the length of time the sutures had been in the tissues, varied between wide limits. The silkworm gut periods varied from three weeks to six years, the catgut from four to five months, and the silk from three weeks to three years. The only serious source of fallacy is the presence of small, air-borne particles of cotton-wool and the like on the surface of the section, since many of these—for example, cotton-wool itself—are optically active. It is usually easy to differentiate. Suture fibers are obviously embedded in the substance of the tissues; extraneous materials lie in a plane above (or below) that of the section, and are seen to be overlapping the cellular structure of the part. Sutures tend to be

focally distributed more or less in relation to scar or granulation tissue, possibly with giant cells in their immediate neighborhood; air-borne fluff may be found on any part of the slide. Very dense fibrous tissue, striped muscle, and the stratum corneum of squamous epithelium, all possess slight optical activity, but the degree of luminosity is so slight and the anatomical arrangements are so obvious that no difficulty should arise. Stewart summarizes his studies as follows: 1. Sutures or ligatures of silkworm gut, silk and linen thread—that is, all the ordinary suture materials except catgut—are intensely active, and the polarizing microscope affords a ready means of determining their presence in tissue sections. 2. These various materials may retain their optical activity in the tissues for years, and in the case of silkworm gut even after the fibres have been broken down into tiny pieces and ingested by foreign body glant cells. 3. Catgut is much less optically active than the other substances named, and the property tends to be speedily lost in the tissues. For this material, therefore, the method may be inapplicable. 4. Ordinary paraffin sections are all that is required for the demonstration of the phenomenon.

5. Loewi's Adrenalin Mydriasis as a Sign of Pancreatic Insufficiency.—W. L. Cockcroft presents the histories of two patients studied in 1914, the publication of which was delayed because of the war. In one case, in which the pancreas was completely free from disease and quite efficient, Loewi's reaction was completely negative on three separate occasions. In the other case, in which the pancreas was almost completely disorganized, the reaction was markedly positive, also on three separate occasions.

Le Progrès Médical.

March 27, 1920, xlviii, 13.

Alimentary Poisons.—Loeper refers to the increasing importance of this subject, which has such multiform ramifications. The first to suggest itself is poisonous mushrooms; even the colleagues of the author, who are both mushroom fanciers and botanists, are repeatedly deceived when they are on their holiday in the country. Most of the confusion is due to two poisonous species which closely mimic edible mushrooms. Next come the species of poison beans which imitate edible species and cause socalled favism. Here belong especially a species of poisonous haricot. There are also poisonous potatoes which may cause solanism. Substances which may obtain poison through their oxalic acid content are rhubarb, sorrel and chocolate. Poisoning from shell fish may be of two types, according as the mussels, etc., are originally sound or diseased. Poisonous fish along the French coast are rare, but the herring is sometimes accused. Meat and milk unless decomposed are seldom poisonous, and when such poisoning occurs there is a special reason—in the case of milk the animal has fed on a poisonous substance—the goat, for example, on the euphorbia. We next pass to the class of decomposed foods, chiefly articles imperfectly preserved, which have been attacked by saprophytes, as caviar. Diseases of cereals give rise to ergotism and analogous conditions. Much food poisoning of various kinds formerly obscure can now be accounted for by paratyphoid fever, especially egg poisoning. In putrid meat numerous complex substances form, not all of which are nitrogenous, which can poison in almost infinitesimal quantities. In some cases these can be recognized by their physiological action as ptomatropine, which behaves almost exactly like atropine. Strangely, the author neglects to mention in this connection botulism. He concludes with food idiosyncrasy and anaphylaxis, the toxic action of mineral matter in food and drink, etc.

Hygiea.

March 31, 1920, lxxxii, 6.

Milk Injections in Infectious Diseases.—Bratt has made a series of intramuscular injections of fresh and boiled milk, including milk from the market which had been boiled four minutes. The latter as a rule caused chills, malaise and high transitory fever and locally swelling, sensitiveness and pain. With fresh milk the results, although of a similar type, were much milder. The total number of cases treated was thirty-eight. One group of eight cases comprised miscellaneous infections—scarlet fever, erysipelas, acute rheumatism, prostatitis, pyelitis, etc. Save for two cases of scarlet fever the material all showed rapid fall of temperature and subjective improvement. The second group was uniform and comprised thirty cases of influenza. In sixteen of these there were seen within three days after injection fall of temperature and collateral improvement. In five cases the improvement followed promptly upon the first injection and recovery after the second injection. This leaves nine others to account for. Of these four were in pregnant women, while the other five showed physical signs of implication of the lungs. Generally speaking, these nine cases were not benefited and two patients died, although two showed transitory response to treatment. Apparently the parenteral injection of milk is of benefit in benign uncomplicated infections, cutting short the process to some extent; but there is no evidence that it possesses any power for good in severe and complicated infections.

Revista Medica Cubana.

November, 1919, xxx, 11.

Twenty Years of Obstetrical Literature in Cuba.—Dr. Huguet y Lopez has found that during the period 1901-1918 some 276 articles on obstetrical subjects have been published by local medical men in the medical press of the island. The number of periodicals involved is 14 and the majority of the articles have proceeded from the pens of thirteen men who are especially interested in obstetrical practice. Five men have written 10 or more articles and three of these over 20. The *Revista Medica Cubana* and the *Revista de Medicina y Cirugia* have published over one-half of the papers. Twenty-one leading subjects have figured with three or more papers each. The favorite appears to be teratology with 16 papers. Eclampsia is represented by 11 and ectopic gestation with 13. Puerperal fever has 8 and cesarean section the same number. Pituitrin is represented by 7 and analgesia by 6 titles, while rupture of the uterus claims the same number, as does also abortion. Multiple births has 7 titles and placenta previa 5. Vicious presentations of various kinds add up to ten, chiefly those of the trunk and shoulder. There were three papers on symphysiotomy and five on forced extraction with three on basiotripsy.

Hospitalstidende.

February 4, 1920, lxiii, 5.

The Pandemic of Influenza in Iceland.—Matthiasson emphasizes three points in connection with this visitation as follows: by means of isolation and quarantine the disease (two waves) was limited to the southern and western parts of the island and about half the population escaped the infection; at the close of the visitation sporadic cases were seen over a period of 2 or 3 months. Some months after the second wave another influenza-like epidemic appeared, which was limited chiefly to children and which spread from the capital over the entire island. The first wave reached Iceland in July, having been brought from England by trawlers. During the first 3 months the epidemic was widely diffused in Reykjavik and here and there throughout the island. The second wave or "true Spanish sickness" reached Iceland on October 20, having been carried there from Copenhagen by the mail steamer. The first wave seems to have been mild and must have exerted an immunizing action on the public. The second wave ran its course quickly and was practically over within a month. No statistics are given for the capital city but in Byen with 15,000 inhabitants there were 260 deaths. By the middle of February the disease was apparently nonexistent, but the quarantine was maintained another month. It was after this period that the third outbreak—if it was realy influenza—appeared in young children as an epidemic bronchitis. The author believes that it was influenzal because of similar behavior after the epidemics of 1890, 1894 and 1900.

Book Reviews.

THE AMŒBÆ LIVING IN MAN. A Zoological Monograph. By CLIFFORD DOBELL, M.A., F.R.S., Assistant Professor of Protistology and Cytology in the Department of Biology, Imperial College of Science and Technology. London, New York: William Wood & Company, 1919.

THE author is not a medical man and has written his monograph from a zoological standpoint. He has had a wide experience in his subject, especially during the war and is evidently a tireless and careful student. Much of his time is devoted to a consideration of the nomenclature of the amœbæ belonging to this group and he presents a strong argument for his ideas, though he is at times forced to make some ingenious twists in order to justify his conclusions. His critical review of the literature on the subject is illuminating and exceedingly interesting, though he does not hesitate to express his disagreement with his predecessors. His words do not indicate that he possesses the judicial temperament to any great degree, but he gives what appear to be excellent reasons for his statements and is apparently very familiar with his authorities. It would require an expert in this particular branch of zoology to construct any argument against him. The genera discussed are the *Entamœba, Endolimax, Iodamœba,* and *Dientamœba* and chapters are added on the finding of amebas in the urine and discussing other ameboid organisms described from man. The work is written in a very fascinating manner and will interest zoologists especially.

PRINCIPLES AND PRACTICE OF PHYSICAL DIAGNOSIS. By JOHN C. DACOSTA, JR., M.D., Ex-associate Professor of Medicine, Jefferson Medical College and Assistant Visiting Physician, Jefferson Hospital; Consulting Physician, Northwestern General Hospital; Fellow of the College of Physicians of Philadelphia; Fellow of the American Academy of Medicine; Member of the American Therapeutic Society, etc. Fourth edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company, 1919.

AS is the case with all new books and new editions of the present time, this fourth edition of DaCosta's well known and highly prized work on physical diagnosis shows the influence of the war lessons. Among the additions to the book treating of subjects brought prominently to notice by war-time experience, we find sections on gas edema, gas pneumonia, the effect syndrome, and aviator's heart. Other additions, such as sino-auricular heart block and hilus tuberculosis, have been made and the discussion of various minor subjects has been modified to conform to the newer knowledge. So long as the succeeding editions of this standard work are subjected to as careful revision as this one appears to have been, it will continue to hold its own as an authoritative treatise on physical diagnosis.

ON GUNSHOT INJURIES TO THE BLOOD-VESSELS. Founded on Experiences Gained in France during the Great War, 1914-1918. By GEORGE HENRY MAKINS, G.C.M.G., C.B., President of the Royal College of Surgeons of England; Surgeon to St. Thomas's Hospital; Honorary Major-General, and late Senior Consulting Surgeon to the British Expeditionary Force in France. New York: William Wood & Co., 1919.

MAKINS' previous book, founded on his experience in the Boer War and entitled: "Surgical Experiences in South Africa," has been very widely quoted and this latest addition to the literature of war surgery should be equally appreciated. In this book almost every conceivable form of injury to the blood vessels has been discussed, both individual blood vessel injuries and those in connection with injuries to nerves and other structures. From his extensive personal experience and also because of his position as Senior Consulting Surgeon to the British Expeditionary Forces, so that all sources of investigation were at his command, Makins is particularly well qualified to cover this very important subject, and he has covered it very thoroughly, as all who read this book must admit.

In the introductory chapter he says of gunshot injuries to the blood vessels that the chief information gained during the present war will be found to consist in "a more accurate knowledge of the signs of injuries to the arteries; such as the indications to be gleaned from an examination of the peripheral and vasomotor nervous system; the value of ausculation, both local over the artery, and of the precordial region; and as to the actual mode of development of some of the consequences of arterial injuries. Further, opportunity has been afforded of judging the effect of obliteration of the main vessels upon the vitality of the parts supplied by the peripheral branches affected, . . . An increase in exact cognizance of the nature of the primary anatomical lesions of the vessels, and in the arrangement of the vessels in relation to the various forms of traumatic aneurysm, has been acquired. Lastly, experience has been gained as to the relative advantages attained by obliteration of the main vessels by ligature, by simultaneous occlusion of artery and vein, and the attempt to maintain their viability by suture, respectively." These observations seem particularly well founded when one comes back to this chapter after finishing the book.

The work covers statistical records as to the distribution and anatomical characters of gunshot wounds of the vessels; symptoms, signs and diagnostic considerations pertaining to immediate and remote periods and in all sorts of simple and complicated cases; methods of treatment in general and with special types of injury to the larger individual vessels as well as of the blood vessels as a whole; finally, there are countless references to series of cases of various types, as well as detailed histories of about one hundred cases, while throughout the book is a running commentary of the very greatest value.

This is a book which should be in the hands of every surgeon who has to deal with blood vessel surgery, traumatic or otherwise.

YEAR-BOOK OF PHARMACY. Comprising Abstracts of Papers relating to Pharmacy, Materia Medica, and Chemistry, contributed to British and Foreign Journals from July 1, 1918, to June 30, 1919. With the Transactions of the British Pharmaceutical Conference at its fifty-sixth annual meeting held in London, July 22 and 23, 1919. Editor of the Abstracts, J. O. BRAITHWAITE. Compiler of the New Remedies Section, THOS. STEPHENSON, F.R.S.E. Editor of the Transactions, C. H. HAMPSHIRE, B.Sc., F.I.C. London: J. and A. Churchill, 1919.

THE contents of this volume are indicated by the title-page as transcribed above. The first part, dealing with the contributions on Pharmacy, Materia Medica and Chemistry, is particularly valuable. The abstracts are well done, and are arranged under the general heads of: Alkaloids; animal products; bacteriological and clinical tests; coloring matters; essential oils; fats, fixed oils, and waxes; glucosides, ferments, and sugars; gums and resins; inorganic chemistry; organic chemistry, and plant analysis. The book is well indexed, but the addition of a table of contents would add to the value of a really useful book.

PRAKTIKUM DER MEDIZINISCHEN CHEMIE einschliesslich der forensischen Nachweise für Mediziner und Chemiker. Von Dr. SIGMUND FRÄNKEL, Professor der medizinischen Chemie an der Universität in Wien. Berlin und Wien: Urban & Schwarzenberg, 1918.

THIS volume is intended for use as a laboratory manual and contains methods for qualitative and quantitative analysis of inorganic substances, for the preparation of certain organic materials, for quantitative organic analysis and some of the methods used in physiological, pathological, and forensic chemistry. It is not intended to present a full set of methods for each examination but only those which, in the judgment of the author, have proved to be the most valuable. The book was published more than two years ago and therefore is not up to date in many instances, but even considering this fact it fails to present methods which we are accustomed to find reliable and convenient. The brevity with which the methods are presented is such that the book would be useful only to a chemist of fairly broad experience. On the other hand, such a chemist would be more apt to desire to consult one of the more complete handbooks, such as Abderhalden's. It is not likely to prove a very popular work.

Society Reports.

AMERICAN ASSOCIATION FOR THORACIC SURGERY.

Second Annual Meeting, Held in Atlantic City, N. J., June 9, 1919.

(*Continued from page* 1023.)

THE PRESIDENT, DR. WILLY MEYER OF NEW YORK, IN THE CHAIR.

III. Pleura; Empyema: 1. Empyema Cases Treated at the Rockefeller War Demonstration Hospital, New York.—Major GEORGE A. STEWART, M. C., of Walter Reed General Hospital, Washington, D. C., said it had been their custom, in empyema cases, to operate as soon as fluid was found in the chest and organism or pus cells could be demonstrated with the microscope, or gross pus found on aspiration. The operation in the majority of cases consisted of rib resection, about 1½ inches of rib being removed. At the time of operation exploration of the pleural cavity and the insertion of tubes was practised, as instillation tubes and not drainage tubes. Instillation of Dakin's solution was started at the time of operation; from 80 to 100 c.c. of solution, in the average case, was given every hour during the day and every two hours during the night, the size of the cavity and the infection present making this change necessary. The pus and secretions after operation were rapidly clorinated by the solutions; all odors disappeared. The patients were placed on full diet and lung exercises were begun as soon as the condition of the patient warranted. Sterilization took place rapidly, in some cases the cavity was sterile in five days. In the first series of cases no secondary sutures were attempted. In the second series secondary closures were made by various methods after sterilization. In 80 per cent. of the cases they had complete success. Dakin's solution, taking care of the excess fibrin formed, prevented thickening of the pleural linings and allowed the lung to expand freely as soon as the cavity was closed. The cases when discharged from the hospital were able to return to full duty. The army and navy cases were returned to full duty and many of them saw overseas duty. Autopsy reports in all fatal cases showed at least one complication, more often two or three, as multiple kidney abscess, tuberculosis, intestinal ulceration, pericarditis, adenitis, etc. In the cases operated on early they did not find many pockets; they did where aspiration had been tried. In the later cases the patient was always in very bad condition and the operation was more difficult because of numerous pockets formed. This was particularly so in the series of 1918, and it was frequently necessary to reoperate for pockets at a distance from the original operation. In the early operation a free cavity was found, and the solution prevented the formation of adhesion with with pockets. After a year a number of these patients had returned for examination. By looking at them without seeing the scar it was practically impossible to say that they ever had had empyema. Their chests were fully expanded. *X*-ray examination showed practically no change in either lung, a few showed a slightly thickened pleura. The *x*-ray examination in the cases of secondary closure showed the lung expanded and filling the entire chest cavity. In the chronic cases the plan had been to first improve the general condition and then to proceed more or less in the same manner as in the acute cases. The case arriving was treated with preliminary sterilization, or better, partial sterilization, later operation, removal of foreign bodies, removal of necrotic rib, excision of sinus tracts, sterilization and closure secondarily. The larger extensive operation in the small series of cases was never found to be required. Streptococcus was the prevailing organism. In the first series where repeated aspirations were tried they came to operation in a moribund condition and proved fatal. In the 1918 series aspirations were done, multiple pockets were formed, one fatal case. This was only a brief sketch of the cases, unfortunately in changing stations it had been impossible to give a complete follow-up record.

2. A Series of One Hundred Consecutive Cases of Acute Empyema.—Dr. WYMAN WHITTEMORE of Boston, Mass., presented, by invitation, this series of 100 consecutive cases of acute empyema which extended over a period of a year and eight months, dating from the middle of last April, 1919. Of these cases 92 were operated on at the Massachusetts General Hospital, and 8 outside. During this time he had operated on every case offered to him with one exception. This one case died within half an hour of the time he was seen. Because these were his own personal cases, he felt that he could criticise the results and mistakes very freely. The three techniques considered in this paper were: (1) Dr. Lilienthal's operation; (2) The Carrel-Dakin technique; (3) The closed suction method. In 14 cases Dr. Lilienthal's operation was performed with extremely good results, 12 of the patients doing very brilliantly. Only 11 cases were operated on by the Carrel-Dakin technique, and the results were not very remarkable. At present he was using this technique only in small encapsulated empyemata. Sixty-six cases were operated on by a closed airtight method. The success of this method and the method itself were his main reasons for bringing this subject before the association. About two years ago Dr. Meyer, in reading a paper in Boston on bronchiectasis, dropped a hint about drainage of the pleural cavity by this method. At about the same time an electrical suction pump was perfected by a Boston surgeon's chauffeur. It had been used in other surgical cases, and he was interested to try it in the acute empyemata. The principles of this method were based on: (1) Early operation; (2) The necessity of allowing the fluid to escape slowly; (3) The sterilization of the pleural cavity, by means of Dakin's solution; (4) The suction of the pleural cavity; (5) The prevention of a considerable pneumothorax. When the cases in which the technique had been carefully carried out were sterile and the sinus closed, the *x*-ray had failed to show any pneumothorax at all in many cases, and in others a very small one in the space between the diaphragm and the costal border. The operation had always been done under local anesthesia, with the exception of two or three children. It had been done with many babies a year or more old with perfect ease. It did not take more than five or six minutes and there had never been any shock. A larger trocar—the canular of which will admit a twenty-one or a twenty-two French catheter—was introduced between the eighth and the ninth ribs after a small incision had been made through the skin and usually the external intercostal muscle. The catheter, being shut off with a hemostat, was rapidly slipped through the canula. At this time the canula was filled with fluid rushing out, and he did not believe that any air could enter into the pleural cavity. The catheter was sewed in tight and connected with a long rubber tube going into a bottle containing water, and the end of the tube was kept under the surface of the water. The success of the after-care depended on intelligent individual treatment. The fluid was allowed to escape slowly, this being regulated by the hemostat. When the fluid had stopped coming out by itself, which in large empyemata might take twenty-four hours, the suction pump was attached and the cavity sucked dry. At this time Dakin's solution irrigations were started and kept up every two hours.

He did not want to give the impression that he considered this method a final cure for every acute empyema, as occasionally there was a case whose count at the end of four or five weeks stayed as high as four or five organisms per field—just why he did not understand. In these cases a rib had been resected under gas-oxygen, and a very small cavity had always been found. When packed open with gauze it had promptly healed. He had found that the best rib to resect was the one just above the sinus, although it was the eighth, as the diaphragm had always been found at the level of the drainage. Of the sixty-six cases, fifty-four got well without further operation. Six needed a secondary operation and promptly healed. Two streptococcus cases had become chronic and left the hospital with small drainage tubes. Four cases died. Three of these he would not have touched had he been anxious about his statistics, as they were moribund

when seen. This series was remarkable for its freedom from complications following operation. Six patients in this series of 100 cases died. Two of them, he was convinced, should not have died. In one of these, death was undoubtedly due to the bad management of the suction apparatus, and in the other case, if the closed suction method had been done under local anesthesia, the patient probably would have been alive to-day. One infant died of cerebral embolus and the other three were moribund at the time of operation. There might be some one who was skeptical as to the efficacy of this method, and to him he would say that even if it had not cured every case it had a distinct contribution to make toward ultimate recovery, as it would often tide a patient over the extreme septic condition, and any operation that was needful could be done later on. In conclusion, he emphasized his firm belief in early operation by means of a closed airtight suction technique, done under local anesthesia, and followed by the intelligent use of Dakin's solution.

3. **The Treatment of Empyema.**—Dr. JOHN A. HARTWELL of New York said the purport of this paper was to call attention to the fact that the pathology of empyema as seen in the pandemic of influenza and hemolytic streptococcus pneumonia was essentially different from that seen under more normal conditions of pneumococcus lobar pneumonia. In the former, the empyema was very often an expression of a general invasion by the streptococcus, it developed while the patient was still desperately ill with the lung and other infections, the fluid for a considerable time was thin and contained a relatively small amount of coagulable matter. Further, while the streptococcus was exceedingly virulent, it tended to die out rather early and hence permitted an earlier return of the pleural surfaces to a normal condition. In this disease the empyema was a menace more because the excessive amount of fluid mechanically embarrassed the respiration of a desperately sick person than because of toxic absorption or immediate irreparable damage to the pleural and pulmonary structures. Therefore, the practice of treating the disease by repeated aspiration to relieve pressure was sound. This procedure, in many cases, might result in a cure, because the thin fluid was completely withdrawn, and if the patient established a satisfactory immunity the infecting organisms died out, the inflammation of the pleura subsided and a restitution to the normal took place. In the latter—true lobar pneumonia empyema—the pathology was essentially different. The disease developed at the end, or after subsidence of the pneumonia, when the patient had recovered from the toxicity of the primary infection. The fluid from the start was a thick pus containing, as a rule, mixed organisms. It was rich in coagulable matter and tended to produce mass fibrin. This spread itself over visceral and parietal pleura, thickened them, and thereby crippled the lung action. The pneumococcus itself tended to die out, but the secondary invaders lived and a chronic inflammatory picture was present. Here aspiration alone failed because it could not completely empty the chest of the thick coagulated bacteria harboring masses. The chest, therefore, rapidly refilled, and in contrast t othe other form of empyema, each time this happened the more were the pleura and the lung damaged. Therefore, aspiration was a failure. A strong plea was made for the differentiation of the two diseases, and for adherence, in the usual forms of empyema, to the pathologically sound treatment of rib resection, ample drainage and an orderly clearing up of the infection while at the same time the recovering lung was aided toward expansion by pulmonary exercises. This expansion took place even in the presence of an operative pneumothorax, unless, as demonstrated by Graham and Bell, the chest opening was unduly large; to be exact, having an area in the adult male of more than 8 square inches. The history of empyema during the past five decades showed that from time to time there had arisen advocates of the socalled less radical forms of treatment, who had enjoyed a short period of success. Failure, however, had always succeeded this period. Gradually, through the constant teaching of thinking masters, this disease had recently been handled along sound lines of therapeutic technique, founded on a full comprehension of its pathology. Any falling away from this would only result in a period of again learning old lessons with its resultant suffering. The argument might be summed up in the statement that no form of treatment for empyema which disregarded the thorough drainage of the chest cavity by a rib resection, and the gradual reexpansion of the lung by respiratory effort, met the requirements. Other means would cure a certain number of cases, particularly in such times as the disease occurred in abortive forms, which it had done during the past two years.

4. **The Treatment of Empyema in the Army.**—Captain CONRAD GEORG, JR., M. C., U. S. A., of Ft. Sheridan, Ill., presented this paper. (See MEDICAL RECORD, November 29, 1919, xcvi, 22, p. 883.)

5. **New Problems in Empyema.**—Dr. EMIL G. BECK of Chicago, Ill., said now that the epidemic of influenza had subsided, there remained an accumulation of chronic suppurations. We had learned and were still learning new things about empyema and its treatment as a result of this last epidemic. It was timely, therefore, to bring this subject before the Association again this year for discussion. The following questions were most pertinent: 1. We should try to explain the great mortality in operations of empyema during the recent epidemics. 2. We should define the term "Empyema." When was a fluid in the chest cavity called and pronounced empyema? 3. Multiple encapsulation of pleuritic exudates, what were the causes? 4. What was the proper procedure in bilateral empyema? 5. We should define the indications for rib resection, aspiration, or other catheter drainage. 6. Let us study the advantages over preepidemic methods. Flush or not to flush was the question. 7. Let us discuss the treatment of the cases which had persisted in drainage of pus after operation and flushing. Since there were only a few minutes allotted to the presentation of each paper, and instead of reading a paper, he would throw on the screen a few slides which would suggest the points mentioned for discussion. He would not try to answer all of these questions, but would initiate the discussion by raising the questions. The high mortality in operations was mainly due to the inability of the surgeons to choose the right time for the operation. As a rule he believed they operated too early, probably in the stage of acute pneumonia with effusion. The effusion was thrown out by nature to immobilize the lung during the acute stage, and in the removal of the fluid the immobilized lung again followed the respiratory movement and thus the condition was aggravated. One might say the surgeons operate on acute pneumonia instead of an empyema, and nobody would think it wise to operate in an acute stage of pneumonitis. The proof of the inference might be gained by reading the report of Major Max Ballin of Detroit of his surgical service at Camp Grant, (*Journal of the American Medical Association*, lxxii, 5, 335), from which the writer quoted: "The results of such early operations in streptococci empyema were so lamentable that the surgeon general sent an empyema commission to Camp Lee to study the question. The report of this commission brought out several points: 'First, not to operate as long as the pneumococci process was in existence. Second, to aspirate if the quantity of serous exudate in the chest was such as to interfere mechanically with respiration. Third, to operate only after the pneumococci process has subsided, when real pus has formed.' These rules were observed in twenty-three consecutive cases at Camp Lee, and there was only one death, whereas previously the mortality had been as high as 50 per cent." Colonel A. Moschkovitz divided empyema into three stages: First, the formative; second, the acute; third, the chronic. He had made one interesting observation, namely, that small perforations from the lung lead to the infection of the pleural sac, just as general peritonitis is due to perforation of some intraabdominal organ. He also regarded the operative treatment in this stage as a mistake, and now that time had given a chance for reflection, it might be put down as law *never operate in the formative stage of empyema*. The word "empyema" was derived from the Greek, *em*-inside, *peon*-pus, meaning pus inside. Only those cases, therefore, should be regarded as empyema in which the exudate was true pus. What constituted pus? We would have

to arrive at some definite rule as to when the fluid might be called pus, semi-purulent, or serous fluid. The term pus had been used in a somewhat indefinite sense, in such descriptions as "a purulent substance," "a sero-purulent discharge" or "a pusy discharge." The fact was that a serous exudate, such as was found in these acute cases of empyema, would gradually become purulent and finally become a creamy thick substance, designated as true pus. At what particular state of purulization should we regard this fluid as pus? In his paper on the "Empyema Problem," he had put down an arbitrary rule for himself, and it might be here considered whether such a rule would stand. If one withdrew about 10 cubic centimeters of this fluid every 24 hours and poured it into a test-tube it would be noted that the sediments of these samples varied. The amount of the grayish purulent material settling at the bottom of the tube would be greater each day, so that the fluid drawn on the tenth day might contain as much as 30 to 40 per cent. of sediment and 60 to 70 per cent. of clear serous fluid. If the fluid withdrawn contained more than 20 per cent. of sediment after standing for 24 hours, it might be considered true pus. He regarded the multiple encapsulation of pleuritic exudates as due to the character of the infection, namely, the streptococcus, which caused adhesions of the lung to the costal pleura. The more acute the condition the more likely that multiple encapsulation would occur. The reason that formerly this condition was not met so often was the fact that one rarely had to deal with very acute pleurisies as one did in these recent epidemics. In some instances surgeons had found blebs on the surface of the lung containing pus. It was likely that these peripulmonic small abscesses did not break and empty their contents into the pleural cavity, but that they became adherent to the costal pleura and gradually enlarged and formed real abscesses. Another reason for multiple encapsulation was advanced by Major Moschkovitz, namely, that when patients were not operated upon, the pleural surfaces would adhere around the accumulations of pus. Bilateral empyema had occurred more frequently for two reasons: In the first place the pneumonia was very frequently bilateral, which was not quite as often the case in ordinary times. Secondly, among a large number of cases it was likely that more than one case would fall into the hands of one man, which in former times was very unusual. He cited the following interesting and unusual case of bilateral empyema in a pregnant woman; childbirth normal during acute stage; recovery. Mrs. S., aged 35 years, developed a severe case of influenza in September, 1918, followed by bilateral pneumonia and consequent pleural pus effusion on both sides. The house physician punctured the right chest repeatedly, withdrawing small quantities of pus. She was then in the eighth month of pregnancy and gave birth to a normal child while both pleuræ were filled with pus. On December 21, under local anesthesia, a catheter was introduced in the interspace of the eighth rib on the right side in the axillary line. This relieved her somewhat, as she was moribund at the time this was performed. She rallied and on January 11, one inch of the right eighth rib posteriorly was resected and a large tube introduced. Stereoradiograms at this time showed that there were multiple abscesses in the left as well as the right side. Temperature kept up from 99 to 101 daily, respirations 40, pulse 130 to 150. On January 14, another operation was performed on the left side, the counter-drainage operation described recently in *Surgery, Gynecology and Obstetrics* (April, 1919). After this operation the lung began to expand and both cavities were injected with bismuth paste. The fever gradually disappeared and patient gained in strength and weight. At the present time both sides were closed and she was gradually regaining her health. Whether there would be any recurrence could not be stated at present. It was not necessary to resect a rib in every case. The treatment with introduction of a catheter through a cannula and gradual withdrawal of the pus by gentle suction should be given a trial on a large scale before deciding that a resection of a rib must be done in every case. The question as to whether flushing would have a permanent place on the treatment of empyema was a large one, and he was sure it would be discussed on the basis of some other papers on the program. His own experience had been very limited, but its greatest utility in the cases in which he had employed it was in the solving of fibrinous adhesions and in decreasing the toxicity of the pus when present, so that the patients were put in better condition for recuperation. The discussion of the after treatment which should follow in the cases which resisted the flushing and operative treatment had been brought before this Association by him last year, and he wished to report progress in this line by citing a few cases. He had demonstrated to this Association a number of cases at the last meeting in Chicago, in which either the bismuth treatment or the skin-sliding operation had been performed to take care of the resistant cases. During the past year he had had a greater opportunity than ever to carry out this treatment in a large series of cases. With proper technique about 80 per cent. of the cases, the residue left over after all the usual methods of drainage and flushing had been tried, were closed by the injection of the bismuth paste. In the remainder, the skin-sliding operation had been employed and carried out with some improvement in the technique. The following improvements had been made in this operation: 1. Instead of taking two or three ribs, he had taken as many as six or seven, so that the the cavity might be most widely exposed. This wide exposure promoted the growth of skin from the edges of the wound. 2. It was not necessary that the skin flaps should cover the entire area of the pleura exposed. He had made them shorter than previously. He had also found that it was better to decide on the size of the flaps after the cavity was fully exposed. In many instances it was necessary to cut away about one-half of the pectoralis major muscle. This would not interfere at all with the function of the arm and would very much aid in the quick regeneration of the skin flap into the cavity. Since his last report this skin-sliding operation had been employed by many of his confrères, and their reports indicated that this operation was more likely to be effective than similar types performed in previous times.

Dr. HOWARD LILIENTHAL said that he had never heard a subject more adequately and efficiently covered than the subject of empyema as Dr. Hartwell had demonstrated it. It was very soul-satisfying to him. Dr. Hartwell had said just what he wanted to say, and had said it better than he could have done. He had had good luck with the chronic empyemas with sinuses which he had treated in France. Among these was a group of thirty-one patients, who had just landed at St. Nazaire from America, with pneumonia and subsequent empyema. All had been operated upon by rib resection drainage and they were poor miserable fellows who wanted to get to the front and who knew they would be sent back to America without having had any war experience. An average of about two months had elapsed since operation. The wounds were infected and all had pyocyaneus. On careful examination ten were selected as proper subjects for surgical operation, the others being treated by various disinfecting procedures. Of these ten he operated upon three by a method which left the chest symmetrical and prevented the necessity of Estlander and other collapsing operations. The remaining seven were operated upon under his direction by Captain J. A. Duff of Baltimore. The speaker had perfected this operation before leaving America and was well satisfied with his results. Only one of the ten cases died. his second one, the cause of death being edema of the opposite lung soon after operation. The remainder of the thirty-one cases, with the exception of two, recovered without operation. One died following operation for a lung abscess of the other side, the other was still in the hospital seven weeks later when he left this hospital. This meant a recovery of over 90 per cent. in the thirty-one cases. All had symmetrical chests. The lung function was restored in all these cases. On his return to America he found that the Empyema Commission had pinned its faith on the Carrel-Dakin treatment and he began to wonder whether he had performed unnecessary surgery. After careful thought it was his conclusion that the Carrel-Dakin treatment would do good only when one could absolutely and completely disinfect every part of the infected chest. Dr.

Hartwell had stated this and he did not need to amplify the point. In the cases of old fibrosis in which the lung had been glued to the back bone, he had had an opportunity to take out tissue and have it examined histologically. It was pronounced absolutely fibrosed. In such a case no matter how forcibly one might blow into the trachea or pharynx the lung would not expand, and if one happened to nick the lung air would whistle through it, demonstrating the patency of the air passages. These were the cases in which the Estlander and other operations and the skin-flap sliding operation were justifiable. But in view of the fact that in all the cases he had had there were only two such, it must be a very unusual condition. In regard to aspiration he believed in withdrawing thin fluid when it was present early in the chest, rather than doing an immediate operation. His method of fluid removal was without vacuum suction. A fine trocar and cannula should be used—never a needle—and a rubber tube for siphonage should be attached to the cannula. Puncture was made at a suitable point and the rubber tube hung down beside the bed, thus acting as the long siphon arm. Gravity was the only suction used. The fluid at first ran out slowly and evenly; then there was in intermittent flow, and finally the flow ceased and air entered the tube in collapse with air in the chest. If one wanted to rest the lung one could draw out the cannula at once. If one wished to expand the lung one could have the patient intermittently strain, with grunting respiration, and pinch the tube during inspiration, letting it go with each expiratory effort. The end of the tube should be submerged, and when no more bubles appeared on expiratory effort the cannula was quickly withdrawn. The method was perfectly safe. A needle was dangerous. If he coughed the patient might pierce his lung with the needle. He could heartily recommend this method of emptying a chest of serum or thin pus. The idea was not original, but the method of carrying it out was devised by him and he believed he was the first to demonstrate the possibility of expanding the lung in this manner.

Dr. Carl A. Hedblom of Rochester, Minn., had felt uncertain as to what constituted the best treatment of acute empyema. He had been greatly impressed by the high mortality in the military camps in the early months of the streptococcus epidemic. He had also been in a quandry often as to the treatment in cases of large chronic cavities with practically complete collapse of the lung. It had seemed to him that the major considerations had been first of all the life of the patient, and second, the expansion of the lung. A year ago he had used the socalled trocar and cannula method with aspiration and irrigation of the cavity with Dakin's solution, in a case of streptococcus empyema. The patient, though desperately ill at the onset, got well. Last November he had begun using the method as a routine in cases of acute empyema and as a preliminary to operation in chronic cavities. As a rule the cavity was emptied of pus at once by aspiration wtih a glass syringe. He was impressed with the fact that if one aspirated two litres of pus one had expanded the lung by a corresponding volume. When the cavity was emptied the lung was practically completely expanded. It could not be otherwise. If air was excluded the lung would remain expanded and probably become more or less adherent, provided secondary pockets did not become walled off. They had tried to obviate this by partly filling the cavity once or twice daily by gravity pressure of a few inches of fluid. By this method they had succeeded in most of their acute empyemas in getting partial—as a rule, probably 90 per cent.—obliteration of the cavity. In the majority of cases some type of operation had been necessary to complete the cure. These operations had been of minor extent. There had not been a single death in any case during the continuance of the closed method. One patient had died while he was making preparations for inserting a catheter. All cases recognized were operated. Some cases of acute empyema were not recognized clinically and were found only at postmortem. The closed method had this to recommend it, that the lung would be expanded in proportion to the volume of the fluid evacuated and that if air could be excluded and reaccumulated pus aspirated, the lung would remain expanded. If the Dakin's solution were brought into contact with all parts of the walls of the cavity pockets would also be obviated. The treatment was especially to be recommended in acute cases with dyspnea and cyanosis with toxemia. In such cases the mortality would certainly be lower following this treatment than following rib resection with its incident pneumonthorax.

Major Ethan Flagg Butler of Walter Reed General Hospital, Washington, D. C., said a large series of cases of empyema had been observed at the Walter Reed Hospital, and as a result of these observations he would speak rather emphatically on the inadvisability of using formalin and glycerin in the pleural cavity. It had led to confusion in regard to the bacterial control of these wounds. Dakin's solution, when introduced into the pleural cavity, expended its chemical energy in approximately ten minutes, and from that time on bacteria might grow in the secretions. Formalin did not expend its energy in that period of time, and when direct smears or cultures were made at the end of twenty-four hours or even longer, the results did not give a true indication of the conditions within the cavity. Enough formalin would remain to inhibit the growth of the organisms. That had been found true from experience. Cases had yielded sterile cultures for a week or longer. They had been allowed to close and had then had recurring empyemas. Case records had shown that again and again. In their series they had to reopen and drain many cases that had been considered sterilized and cured by formalin and glycerin. Large amounts of pus and living organisms had been recovered on these secondary operations. In cases where "closed tube" drainage was used secondary complications and recurrences had been noted in a sufficiently large number of cases to raise a question as to the advisability of that method of treatment. Negative pressure, if it be continuous, was a vastly different proposition from the intermittent effect that was gained by the "closed tube" procedure. In regard to the cases of chronic empyema, which they were treating at the present time, they had noticed four main reasons for their chronicity: mechanically imperfect drainage, necrosis of the ribs, occurring in some cases after even a simple intercostal thoracotomy; pleuro-pulmonary communications or bronchial fistulæ; foreign bodies. They had endeavored to meet the situation created by these cases by an intensive use of Dakin's solution—meaning by Dakin's solution the solution of sodium hypochlorite conforming to the requirements as to strength and reaction as defined by Dr. Dakin—and only using it after careful surgical preparation of the case. It was valueless to try to effect chemical sterilization if foci of infection were still active. From 100 to 150 c.c. of Dakin's solution were given hourly by day and two hourly by night. It was too early to state what the final results would be in the whole series, but a small group had been so treated in March, and the following results had been obtained: The group consisted of 21 cases; 15 had no pleuropulmonary communication, and of these 8 had their tubes removed, after a week of sterile cultures, in an average of 23½ days after commencing the intensive irrigation, and the wounds were allowed to close spontaneously. Of the 21 cases 6 gave evidence of pleuropulmonary communication. The communication ceased to cause trouble in 4 of these cases, and in 2 it was possible to remove the tubes, after a week of sterile cultures, in an average of 25 days, the wounds closing spontaneously thereupon. A larger series of 150 cases were under observation at present, but it was too early to say what the final accomplishments would be in this series.

Major George A. Stewart of Walter Reed Hospital, Washington, D. C., said the Carrel-Dakin method was frequently misunderstood, especially the first step or the preparation of the wound for the reception of the Dakin solution. The wound, or in empyema cases the empyema cavity, was the test-tube of a chemical experiment and must be prepared to receive the chemical, Dakin's solution. With sinus tracts leading to pockets one could not expect Dakin's solution alone to take care of them; an operation was necessary first. It was surprising to go into hospital after hospital and see attempts to use the Carrel-Dakin method or rather to use Dakin's solution. They did not know what Dakin's solution

was and very little about how to use it. Until one knew the principles of the method one was not in a position to judge the results one might obtain with a hit or miss use of Dakin's solution. As Major Butler had said, we could not expect to do the impossible. The Carrel-Dakin method in empyema cases would not cure 100 per cent. of cases. It was a valuable addition, used correctly it gave good results. The extensive operation described by a previous speaker was not always successful, as shown by one case at least. This boy was operated on by the previous speaker while in France and returned to this country with a cavity containing 250 c.c. of pus, this after a most extensive operation. Under treatment this cavity was reduced to one containing 50 c.c. at the time the hospital closed. In any discussion of the Carrel-Dakin method it must be remembered that it meant something more than pouring Dakin's solution into the wound or the empyema cavity in this case. One should not attempt to cure one's cases by merely using a solution. One could not cure a hernia by ligation of the sac and a skin suture; neither could one cure empyema by pouring in a solution without an understanding of the principles involved.

Captain Conrad Georg, M. C., U. S. Army, General Hospital No. 28, Ft. Sheridan, Ill., thought a great deal had been said during the discussion of this subject concerning the use of Carrel-Dakin solution. It had been stated that good surgery and the proper preparation of the cavity was a part of the Carrel-Dakin technique; this was not true because good surgery had been used in the treatment of empyema long before the Carrel-Dakin technique was developed. We all knew that it was good surgery to remove a foreign body if it was the cause of the empyema. Drainage of secondary abscesses was also required before the Carrel-Dakin or any other treatment was used. There were cases at General Hospital No. 28 which had been treated by the Carrel-Dakin method and allowed to close spontaneously and later on had to be opened up again. Furthermore, in a series of fifty chronic cases operated upon overseas or at other military hospitals in this country, in which there was pus still draining so that further treatment was required, some having been treated by the Carrel-Dakin method and some by rib resection, the Carrel-Dakin treatment was continued until it found that the cases became stationary, as shown by the fact that the discharge continued and the patients did not get well. During this stage of the disease the use of formalin-glycerine gave very good results. They had not had to do a rib resection in any case in which this treatment had been carried out. Some cases required rib resection for other reasons than the infection itself, for example, when a foreign body was present or when there was inadequate drainage. Of course a foreign body might have to be removed whether one used the Carrel-Dakin, formalin-glycerine or any other method of treatment. The results were always satisfactory when the removal of all sources of infection was properly carried out, foreign bodies removed and pus pockets that formed aside from the general cavity aspirated.

Dr. James F. Mitchell of Washington, D. C., said the experience of the Empyema Commission was interesting because it covered both acute and chronic cases. They arrived at Camp Lee just in the middle of the empyema epidemic in 1918, and had there a series of 140 cases, all due to the hemolytic streptococcus. There were no exceptions. The reports showed that at first there was a terrific mortality and that all operated cases died. Gradually the mortality declined to about 40 per cent. The Carrel-Dakin method had been tried and discarded as worthless. Operation was done as soon as fluid containing streptococci was found and a rib resection was always made and adequate drainage established, and under this method the mortality was about 40 per cent. At first they were merely observers. Finally they were given entire charge of the cases. During this period they had a series of twenty-three cases with one death. These cases were all extremely sick men, terrifically ill, and it soon occurred to them that a much better procedure was to try and get these ill men into the condition to which we were accustomed in civil life. The matter had now been threshed out and he thought it was generally agreed that if one aspirated and tided the patient over his virulent active pneumonia until he got up some resistance, then operation was attended with better success. They had immediately started aspirating frequently. As soon as the chest would fill up they would aspirate, and finally when frank pus was obtained they would operate. Whether resection or intercostal thoracotomy was done, mattered little. After operation they had used suction and forced Carrel-Dakin treatment, and the results were wonderful. The one case lost was a case of pericarditis, and both pericardium and pleura were drained. This man promptly died of a streptococcus septicemia and pus was found about his liver and spleen. The process had passed through the diaphragm on both sides. They had wasted some time in the chronic cases which had survived operation and were still draining, in testing out the various solutions and trying different methods. They had given Dichloramin-T a long trial and had abandoned it. They had concluded that the proper application of the Carrel-Dakin treatment gave the best means of treatment at our disposal, and he thought the points brought out by Major Stewart and Major Butler were very important in this regard. The Carrel-Dakin treatment was not a cure all, and to use Carrel-Dakin did not mean all; one must have the real, genuine article. The use of frequent flushings, recognizing the fact that the chemical life of the solution is extremely short, was an essential point. The socalled closed method with infrequent injections of small amounts of the solution had never appealed to them at all. In the chronic cases, aside from the removal of foreign bodies, the thorough exposure of the cavity for the application of tubes and the reception of the solution was the most important thing. This was very well illustrated in the second series of 160 cases at Fort McPherson. In August he had had cases running from the previous November, and a thorough opening of the cavity for the reception of the Dakin solution was the procedure adopted. Some cases had had extensive operations, plastic procedures on the chest wall, or decortications, and the results that he saw there were not good in that line. It was found that by preparing the cavity, getting rid of sinuses and obtaining a free opening for ample flushing, and the application of the Dakin solution, many of these cases got well. They had operated on a number of them in this way. It was nothing new, simply getting at them. Late results at Camp Lee and Biltmore had demonstrated the practicability of one thing which he had opposed at the beginning of their experience, but which was insisted upon by Dr. Moschcowitz, namely, leaving an actual cavity in the chest and allowing the chest wall to close. The results were startling by getting the cavity clean first and then allowing the chest wall to close. To see these cavities gradually disappear and the apparently hopelessly thick pleura come out and fill up the chest was a remarkable experience. In all this series of cases they had had no big disfiguring operations. The fact brought out by Dr. Moschcowitz that the cavity would take care of itself should lead one to avoid a great many of the larger operations. They had had experiences with bismuth paste, which called for warning. It was not the bismuth paste, it was the method of application. At McPherson, in one instance, he had removed something over a pint of bismuth paste, which had been forced in with the hope of curing an infected cavity. It made a terrific complication when one had to dig it out of the chest. The late history of these cases would be extremely interesting. The recent epidemic of influenza was an example of this point. He had learned from McPherson that the old empyema subjects were extremely susceptible and numbers of the apparently healed and well cases had died from influenza. One of the most interesting cases opened up an important field, that of transfusion of blood. A man operated at Camp Lee in February had come under their care in April. He then had a cavity in his left chest which held about two litres. He had streptococcus infection of his right wrist, elbow, and back, and innumerable abscesses over his body. He was practically dying from February to June when he was moved to Biltmore. He was then in much the same condition. Then a single transfusion was made from a recovered case of empyema.

and from that day the man proceeded to get well. It gave him resistance, and in ten days he was sitting up, eventualy his cavity was sterilized, and the chest wall was allowed to close. He was now well.

Dr. JOHN A. HARTWELL of New York judged that his language evidently had not been clear in reference to the Carrel-Dakin. He did not mean to give the impression that he did not approve of the Carrel-Dakin treatment; he did approve of it, with the restrictions which Major Butler had put upon it. He did not think it a cure all, and he did not think it should be so relied upon. It was doing throughout the United States at the present time more harm than good because so many men who did not comprehend principles were using it inadequately and improperly and wondering why they did not get good results. They were relying upon it to do the impossible. That offset its undoubted value when rightly used. The second point which he had brought out was the postoperative treatment. Close supervision was the most important factor and was being generally neglected in very many hospitals. He did not mean the members of this association, who were all trained thoracic surgeons, but he meant other men who had recently had the responsibility of taking care of a large number of these cases and had never enjoyed full training in thoracic surgery. These patients remained in bed for a few days after the operation and it would be noted that they would lie and sit in an improper attitude because the position was more comfortable. If allowed to remain that way they would have more or less permanent defect in a curve of spinal column. He ventured to state that one might go through any of our hospitals, where many cases of empyema were found, and by standing them on their feet and placing a straight edge down their backs one would find this condition. An essential part of the treatment, therefore, began in maintaining proper attitude with a straight spinal column and the orderly expansion of the lung on the part of the patient, usually by calisthenics and blow bottles, as soon as the patient was able to undertake that effort. If this were done results would justify it. He asked that the members of this society watch the younger men throughout the country and caution them against the neglect of this very important treatment.

Dr. NATHAN W. GREEN of New York thought the subject altogether too wide for one to cover it in a short discussion. He could add to Dr. Hartwell's suggestions that perhaps the Carrel-Dakin method was blamed for doing a great deal of harm. It was not the Carrel-Dakin method which was doing harm, but the ignorance of the medical mind; all knew that many medical minds were not schooled to think analytically. The attempt was made to improve on the matter, with the result that the essentials were not carried out. His experience with internes was that they attempted to carry out this method in some way to conform to their own ideas, instead of taking this beautifully crystallized procedure that Dr. Carrel had worked out; they went ahead in a slipshod way and could not see why they did not get good results. Everyone had spoken of the empyema of influenza; it was a very acute streptococcus infection. The early operations upon these had been very fatal, pus had not been found until late. One thing had been impressed upon us during the last year, viz., that an empyema was not an emergency and did not call for immediate operation. One could tide over the critical condition by aspiration and then if it did not clear up one could go in with Kenyon's drainage, or by taking out a rib, or doing Lilienthal's procedure upon it. But the first thing to do when empyema was acute was to consider well the general condition and the second thing was to allow it to become subacute before operating. One could do a tapping any time when one first discovered it. Where the pus was thick the procedure differed from that in which it was thin. When one got an acute streptococcus infection there was a thin pus that would draw off through a tube no larger than a little finger. The Dakin solution helped to bring the lung down because it had proteolytic action and tended to thin out the adhesive lymph exudate. The bacteriology of infections ought to be worked out more thoroughly. The average interne did not appreciate the bacteriology of infections. He let most of the pus that comes out of abscess cavities get wasted. The speaker had tried again and again to get the internes to culture the pus from various cavities, but generally it was reported sterile pus. One would know better how to treat a case if one knew the bacteriology. Streptococci would rarely cause metastatic abscesses. Intelligent treatment early was the key to success in empyemata, and there could not be intelligent after treatment unless one kept after the interne and nurse who were following it up. Dr. Mitchell had spoken of chronic cavities reducing in size; cases which one would think would have to have a further plastic would often close entirely without more ribs being taken out or further plastic operation being done if the drainage was adequate and blow bottles were used faithfully. This was something one should bear in mind, and one should put in a good sized tube and drain and wait to see if the lung did not come down.

Dr. HEYD asked Dr. Hedblom if he had understood him correctly when he stated that in his cases of empyema there had been no deaths.

Dr. HEDBLOM replied that since November, 1918, there had been no deaths in cases treated by the closed methods during the continuance of that treatment.

Dr. LILIENTHAL asked Dr. Hedblom what class of cases he had dealt with. Were they the kind that originated about Rochester? One hundred per cent. of cures was so astonishing that he thought the association ought to hear all about it.

Dr. HEDBLOM was sorry he could not give a detailed report, but he could easily get the case numbers of all the cases he had had. The patients were mostly from the middle west, some from more distant points east and west. There had been a small mortality in empyema cases but none in the acute cases treated by the closed method during the continuance of this treatment. In several chronic cases the patients had died of pneumonia. One had developed brain abscess following rib resection for drainage of residual cavity. There had been some instances in which the treatment had to be changed owing to development of bronchial fistulas or hemorrhage, or both, but none of these patients had died from the complications. Several had become chronic and had required prolonged treatment.

Dr. WILLY MEYER of New York had frequently wished, in the course of the last two years, to be called into active service. It must have been fascinating to treat "*a series of early cases*," occurring in strong younger men, an experience of which Dr. Mitchell had just given such an excellent report. All knew what an amount of good the Rockefeller War Hospital had done for the medical profession and for suffering mankind. In the hospital with which he was connected they were most grateful to Major Stewart for having allowed their doctors, chemist, and nurses to get there a thorough training, as quickly as such a training could be had, in the proper application of this method. As much as he had seen, he would subscribe to what Dr. Stewart and Dr. Butler had stated; it must be "Dakin's fluid" that one used, and its application must be properly, faithfully, and enthusiastically carried out. He recalled, to illustrate, the case of a man in whom bismuth oil had been injected for showing the extent of an old empyema cavity. The doctor who used it had read about the good roentgenographic result of the same. Here the "clinical" result was a pronounced bismuth-poisoning and the repeated *x*-ray showed that there was a big deposit way up in the chest. The case had been originally operated on months ago. He had great difficulty in removing this bismuth oil. After a severe reaction the patient soon had a steady evening temperature of almost 102° and was generally sick. Then they used Carrel-Dakin. It was a revelation. He was sure that no other solution could have effected such a complete change of the picture within twenty-four to thirty-six hours. The temperature dropped quickly to normal and remained normal, and the patient declared that he had never felt better. He agreed with Major Hartwell that we must teach the younger men to use it thoroughly and correctly, and certainly never to throw it overboard. These cases were hospital cases; they should not be treated privately—a point that should be emphasized—unless the patient had most

faithful nurses and could get the solution freshly prepared every day. Before using Carrel-Dakin he had followed the late John B. Murphy's advice and injected formalin-glycerine. He had seen results from it that other antiseptics had not given. One word about blowing up the lung at once after the evacuation of the empyema fluid. Several years ago he had taken a boy to the differential pressure apparatus, had made an incision, had evacuated the fluid and had blown up the lung. It was most interesting to watch how the lung gradually came up to the surface. He confessed that he had felt his heart beating a number of times faster in doing this. In a child of seven years they had ventured to use plus 14 to plus 16, before he ordered the further increase in air pressure stopped. He could see that 16 plus did not do more than 14. It proved the still present inflammatory infiltration of the lung, which latter organ stayed away from the chest wall about 1½ inches. They covered the wound with sterile rubber-dam and applied a dressing. For almost fourteen days the little patient was in a happy condition, up and about with normal temperature. On the twelfth or thirteenth day, the temperature went up to 104°-105°. He thought of retention of secretion. Under differential pressure he made the first change of dressing. There was no discharge. Again he slowly blew up the lung, when, suddenly there spurted a fountain of serosanguinolent fluid, surely 12 to 15 inches high. The cause of the fever had been retention. The patient made a quick recovery. He had had a similar satisfactory experience with this method in a second child. There often existed lung infiltration after pneumonia which only gradually dissolves.

Most interesting to him was the statement that in spite of a surely present pneumothorax the external wound healed and the throax remained closed. He had had the same experience lately in a child with old empyema fistula. The impression he had after listening to the experiences of Drs. Whittemore and Hedblom, and from what he had seen personally in the after-treatment of thoracic operations he firmly believed in draining *"every case"* of thoracic operation, inclusive of empyema. Not only should one drain, but one should drain *"air-tight."* Those who had the privilege of working at the battle front and behind it, had seen that complete closure of the throacic wound was of great benefit to the patient. It stood to reason that if one could add to air-tight closure a proper and air-tight thoracic drainage, it must mean a tremendous step forward in the after treatment of throacic cases. No matter what kind of thoracic case had come under his hands, whether an exploratory incision, a resection of the chest wall, a lung case or an esophageal resection, in every instance he drained, and drained air-tight. From this point of view he ventured to say that, if called upon to treat *"an early case"* of empyema, it would be an advantage to let out the fluid, install air-tight drainage and make the tube dip into the water, thus syphoning the cavity. Every one of us should study the splendid paper of Graham and Bell (*American Journal of the Medical Sciences*, December, 1918). What they said on the basis of careful experimentation, must open the eyes of every one. From this point of view the experience of Dr. Whittemore and Dr. Hedblom seemed to him to be of great importance. We must learn to find out which case of empyema could be subjected to the closed operation to advantage, and which must be operated on and drained according to the older methods.

(*To be continued.*)

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, April 28, 1920.

THE PRESIDENT, DR. HERMAN B. ALLYN, IN THE CHAIR.

The Postinfluenzal Chest.—Dr. ARTHUR C. MORGAN presented two young men demonstrating the points he desired to develop. He confined himself chiefly to the physical signs in the chest, with their interpretation bearing upon the differential diagnosis between pulmonary tuberculosis and post-pneumonic pathology. The primary and chief pathology of the lungs in pulmonary tuberculosis, he said, was located in the apex and progressed downward and outward by continuity of structure. In an ordinary case of lobar pneumonia, the usual pathology was located at the base of the lungs, more frequently on the right side. In postinfluenzal pneumonia, especially following the epidemic of 1918, evidence of post-pneumonic pathology might be shown in either the upper or lower portion of the chest. When affecting the upper portion it might be confused with pulmonary tuberculosis, in which the lesion was apical and spread by direct extension. In pneumonia it might have been localized or generalized, and its after effects were patchy areas of relatively normal tissue between. In tuberculosis the pathology was progressive. In pneumonia the pathology was most severe during the height of the attack. The clinical symptoms in tuberculosis become progressively marked and more severe, which was just the reverse in post-pneumonic conditions. Patches of adhesive pleurisy or of localized empyema were more frequent posteriorly, their frequent sites of location being subscapular, high up or under the axillary space, or at a point one or two interspaces below the inferior border of the scapula. These areas could be determined by physical signs, confirmed by exploratory puncture with the needle and after removal of only a small amount of pus the condition would frequently go on to recovery without further operative interference. Adherent pericardium to lung or diaphragm might be detected by a peculiar tugging sound on auscultation after having the patient hold his breath following deep inspiration, differing from a physiologic rhythm disturbance of the heart as was sometimes seen physiologically. This was confirmed by the fluoroscope.

Dr. JOSEPH SAILERS said the postinfluenzal conditions were largely governed by the fact that the influenza organism, whatever it might be, seemed to predispose to subsequent infection. These infections were usually either of the streptococcus or pneumococcus variety, and when they occurred they were to be treated as such without reference to the preceding influenza, excepting in so far as it appeared to increase the severity of the disease. He could not agree with Dr. Morgan that postinfluenzal pneumonias were almost invariably at the base of the lung. He could not recall the exact figures because his records, unfortunately, were sent to Washington before he could get hold of them all, but he would estimate that at least one-third of the pneumonias that followed influenza were in the upper lobe of the lung. Empyemas were common and were invariably streptococcic or pneumonic. Very frequently they occurred in the interlobar space and were nearly always encapsulated. Only a smaller proportion were the massive empyemas found after the acute croupous pneumonia. In one case there seemed to be a typical postinfluenzal pneumonia. During the course of the disease the Pfeiffer bacillus was found in pure culture in the sputum and at the autopsy obtained in pure culture from the tissues of the lung. In reference to tuberculosis, it must be obvious that the attacks of influenza did not actually cause the subsequent attacks of tuberculosis. There must have been an infection previously existing but latent, which the influenza organisms, in common with all the other organisms causing acute inflammatory conditions of the lungs, rendered active. It was conceivable, of course, that the patient might be infected upon a damaged lung with the tubercle bacillus subsequent to the attack of influenza. He had not, however, ever seen a case in which this appeared to be likely. He merely did not deny that it could occur. Returning to Dr. Morgan's paper, he emphasized the fact that a careful physical examination was the most important feature in the diagnosis of pulmonary conditions, and particularly a careful inspection. The methods that Dr. Morgan had suggested of placing lines on the lungs in order to detect localized restriction of movement seemed to him particularly good. He had not used it, but expected to do so in the future. It was not, however, impossible to recognize localized restriction by careful inspection, and he thought of all the methods of diagnosing, careful inspection of the thoracic movements was perhaps the most frequently neglected. As for the other postinfluenzal conditions such as bronchiectasis, fibrosis, etc., they were usually not manifest immediately after the

disease, particularly bronchiectasis, and it must always be a question, at a later stage, whether the attack of influenza was directly responsible.

Dr. F. F. BORZELL believed there was perhaps no other acute respiratory infection resulting in more varied pathology, immediate and remote, than influenza, or so-called influenzal pneumonia. With the "flu" infections they found a condition, primarily starting in one or both hiluses, but giving a picture during the height of the attack of varied distribution. Complications might be divided into immediate and remote. The immediate conditions more often found are areas of delayed resolution, pulmonary abscess, interlobar empyema, encysted empyema, pleural thickening, pleural adhesions, pericardial adhesions or mediastinal adenitis. It should be emphasized that studies in the infection should be both radiographic and radioscopic. A most important phase was seen in the patient who presented himself to the physician because of persistent ill health. Probably the problem most frequently confronting the pathologist was that of differentiation between beginning pulmonary tuberculosis and uncomplicated post-influenzal pathology. Careful stereoscopic study of the chest, however, would, if tuberculosis were present, clearly show the lesion.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEBRASKA STATE BOARD OF MEDICAL EXAMINERS.

November, 1919.

(*Concluded from page* 982.)

GYNECOLOGY.

1. Describe the operation of curettement. When is such an operation necessary?
2. Differentiate between uterine tumor and pregnancy.
3. Name five diseases peculiar to women and two causes of each.
4. Describe in detail the phenomenon of menstruation.
5. Define vulva, clitoris, labia minora.
6. What is meant by circumcision of a female? When is the operation necessary?
7. Diagnose and treat a case of vaginismus.
8. Diagnose and treat elephantiasis and varicose veins.
9. Name five malformations of the vagina.
10. Diagnose and treat (a) cystocele and (b) retocele.

SURGERY.

1. Define a tumor and name four varieties of malignant and four varieties of benign tumors.
2. Differentiate between carcinomas and sarcomas and name two varieties of each.
3. Describe a hernia, give some of the predisposing causes, and name six varieties.
4. Describe the aseptic and the antiseptic methods of treatment of wounds.
5. How would you operate for the radical cure of complete fistula in ano?
6. Give symptoms of gallstones in the common duct and your method of treatment.
7. Give the differential diagnosis between fracture of the neck of the humerus and dislocation of the shoulder joint.
8. What is Colles' fracture and how would you treat it?
9. Define a dislocation and give two exciting causes for dislocations.
10. What are the symptoms of septic surgical fever?

ANSWERS.

GYNECOLOGY.

1. *Curettage.* All antiseptic and aseptic precautions are necessary, the patient should be in the dorsal position, the vagina is to be disinfected, and the cervical canal dilated; a speculum is introduced into the vagina and the cervix is drawn down with volsella; the uterine cavity is irrigated with solution of creolin or lysol; a curette is inserted to the fundus and moved down to the internal os; the operator should begin at one cornu and go in the same direction all around till he reaches the starting point, and if necessary repeat till no more spongy or hyperplastic tissue appears; the fundus should be scraped separately by moving the curette along it from side to side; in going towards the fundus no scraping should be done, and care must be taken not to perforate the uterus; should this happen no fluid must be injected; otherwise the uterus and vagina are again irrigated, and one or more strips of iodoform gauze are inserted into the cavity to act either as a hemostatic plug or as a drain, which is diminished with two days' interval and withdrawn on the sixth day. A hemostatic tampon should be placed in the vagina and withdrawn the following day. If any fever arises, the tampon is at once removed and the vagina douched with antiseptic fluid every three hours. If not, the vagina is only swabbed with the same every day, and packed loosely with iodoform gauze. After the final removal of the gauze the antiseptic douche is given twice a day until there is no more discharge. The patient should remain in bed for a week.

Curettage is indicated: (1) For removal of placental débris (2) hemorrhagic endometritis, (3) in some forms of dysmenorrhea (membranous), (4) for diagnostic purposes, (5) in some cases of puerperal sepsis, (6) sometimes to check hemorrhage, due to fibroids.

2. *Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine tumor (for example, fibroid): Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

3. FIVE DISEASES PECULIAR TO WOMEN.—(1) *Salpingitis*, caused by sepsis, or gonorrhea; (2) *Endometritis*, caused by sepsis, or gonorrhea; (3) *Displacements of the uterus*, caused by adhesions, or congenital deformity; (4) *Abscess of Bartholin's gland*, caused by gonorrhea, or sepsis; (5) *Uterine fibroids*, cause unknown.

4. *Menstruation* is a periodic discharge of blood from the mucous membrane of the uterus, due to a fatty degeneration of the small blood-vessels. Under the pressure of an increased amount of blood in the reproductive organs, attending the process of ovulation, the blood-vessels rupture, and a hemorrhage takes place into the uterine cavity; thence it passes into the vagina. Menstruation lasts from five to six days, and the average amount of blood is about five ounces. It begins at puberty and occurs periodically at about 28 days interval, until the menopause; it is absent during pregnancy and early lactation.

Changes in the uterus during menstruation. "The endometrium, in the four or five days preceding the flow, becomes rapidly thicker and its superficial layers are congested with blood and, in places, small collections of blood may be noticed. Opinions differ very much as to the change undergone by this thickened membrane during the flow. According to some authors, most of the membrane is thrown off and the blood escapes from the denuded surface mixed with pieces of the membrane. According to others, no material destruction of the membrane occurs, the blood that escapes being due to small capillary extravasations or perhaps mainly to a process of diapedesis. It would seem that the amount of destruction of the endometrium must be subject to individual variations. After the cessation of the flow the mucous membrane is rapidly repaired by regenerative changes in the tissues; the surface epithelium, if denuded, is replaced by proliferation of the cells lining the uterine glands and the thickened, edematous condition of the membrane rapidly subsides during a period of six or seven days. The mucous membrane of the uterus may be said to exhibit a constantly recurring menstrual cycle which falls into four periods: (1) Period of growth in the few (five)

days preceding menstruation, characterized by a rapid increase in the stroma, blood vessels, epithelium, etc., of the membrane. (2) The menstruation or period of degeneration (four days) during which the capillary hemorrhage takes place and the epithelium suffers degenerative changes and is cast off more or less. (3) The period of regeneration (seven days) during which the mucous membrane returns to normal size. (4) the period of rest (twelve days) during which the endometrium remains in a quiescent condition."—(Howell's *Text-book of Physiology.*)

5. *Vulva* is the name given to the external organs of generation in the female, including the labia majora and minora, hymen and clitoris.

Clitoris is a small erectile organ, analogous to the penis in the male, but does not contain urethra or corpus spongiosum.

Labia minora are two triangular folds of tissue situated between the upper part of the labia majora.

6. *Circumcision in the female* consists of separation of the adhesions between the hood or prepuce of the clitoris and the glans clitoridis, and removal of the redundant prepuce. The operation has been recommended by a few as a cure for masturbation.

7. *Vaginismus* is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. The slightest touch causes painful spasms, and examination may be impossible without an anesthetic. Its *causes* are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, carunculæ myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

8. *Elephantiasis of the vulva.*—"This disease, primarily a chronic recurring lymphangitis, may be associated with hyperplasia of the connective tissue, skin, mucous membrane, and epidermis of the vulva. The whole process results in the formation of a tumor, sometimes of large size, and most frequent between the years of puberty and the menopause. An organism called the *filaria sanguinis hominis* is found early in the disease in the lymph-vessels of the affected part, and is the exciting cause; it may not be found later, for the vessels are blocked by fibrous deposit. The tumor may involve the whole or a part of the vulva, most frequently the two labia majora, less frequently the clitoris, and least frequently the nymphæ. The growth, when large, is apt to be quite pendulous. The surface may be smooth, rough, fissured, warty, or ulcerated. The tumor, especially if ulcerated, gives forth a sero-albuminous exudate, which may be so profuse as to demand frequent change of clothing. Ulceration is common as the result of friction. Both labia are involved simultaneously. The inguinal glands on both sides are enlarged. Chyluria is a frequent complication. The disease does not directly impair the general health; it is, however, disabling from its mechanical interference with urination, walking, and coitus.

"*The treatment* is excision. The numerous dilated lymph channels increase the danger of septic absorption, and in the operation renders the most extreme asepsis imperative."—(Dudley's *Gynecology.*)

Varicose veins of the vulva.—"Varix is an aggregation of dilated or varicose veins in the erectile tissue of the bulbi vaginæ. The varicose state is caused by obstruction to the circulation. This obstruction often arises from direct pressure upon the venous trunks by the gravid uterus. The pressure may be exerted by tumors or by inflammatory exudates. Habitual constipation, portal obstruction, and visceral disease may underlie and perpetuate the disorder; it belongs rather to advanced than to early life. The tumor is oval, globular, or serpentine, and may grow to the size of a child's head. The surface is irregular and of dark-blue color. The mass temporarily disappears on pressure. The subjective symptoms include a variable pruritus and, especially on walking or standing, a sensation of fulness and weight. Rupture of the distended veins often occurs during parturition; it may be the result of traumatism or may be spontaneous. External rupture may cause dangerous, even fatal, hemorrhage. Subcutaneous rupture into the cellular tissue gives rise to an accumulation of blood called hæmatoma.

"*The treatment* includes mechanical support of the uterus, if displaced, regulation of the bowels, removal of waist constriction, the application to the varix of a pad held in place by a T bandage, the use of astringent lotions, and, especially during pregnancy, frequent rest. The radical surgical treatment is the same as would be indicated by the general principles of surgery for varix in any other location."—(Dudley's *Gynecology.*)

9. *Five malformations of the vagina.*—Double vagina, absence of vagina, persistent cloaca, stenosis of vagina, and the presence of blind pouches or canals in the vagina.

10. "*Cystocele* is really a hernia of part of the bladder into the vagina, the vagina mucous membrane forming its outer covering; or it may be expressed as a deflection of the vesicovaginal septum toward the vagina. It forms a smooth rounded swelling, which bulges through the vulvar aperture when the patient coughs or strains.

Rectocele is a hernia of the rectum into the vagina, covered by the mucous membrane of the posterior vaginal wall. It forms a swelling resembling that produced by a cystocele, except that it is on the posterior aspect of the vagina. If the finger be introduced into the rectum it can be passed into the pouch in the vagina, and similarly a sound introduced into the bladder can be passed into a cystocele. A rectocele is nearly always associated with a deficient perineum; and, further, cystocele and rectocele are often found together. When this is the case the vulvar outlet, when patient strains, is occupied by two smooth swellings placed one in front of the other; between them the finger can be passed up to the cervix."—(Sutton and Giles' *Diseases of Women.*)

For radical cure of cystocele.—"The patient is placed in dorsal position. The posterior vaginal wall is kept out of the way with a weighted speculum. The cervix is drawn down with a bullet-forceps. With a pair of tenacula the sides of the prominence are drawn together in the median line in order to see how much of the wall is redundant and these points are marked with small nicks. Next, the whole surface is put on the stretch between four pairs of forceps—one at each of the sidemarks, one near the cervix, and one at the transverse ridge at the inner end of the urethra. With a pair of scissors curved on the flat, a strip about ¼ inch wide is cut out of the mucous membrane. Similar strips are removed on both sides until an oval is denuded. Finally a running suture of chromicized catgut is passed under the whole pared surface, uniting the edges from side to side." If necessary, a perineorraphy should be done at the same time.

Operation for rectocele.—The operation of posterior colporrhaphy is thus described by Sutton and Giles: "The patient is secured in the lithotomy position, and the vagina thoroughly exposed with retractors. An elliptical incision, one end of the major axis being close to the cervix, the other near the vulvar orifice, is made in the mucous membrane of the posterior vaginal wall, taking care not to cut deeper than the recto-vaginal septum, lest the bowel be opened. The vaginal mucous membrane is then cautiously dissected off; the amount to be removed is estimated by the laxity of the parts and the degree of narrowing which the operator regards as necessary to meet the needs of the case. After removing the vaginal wall and securing the bleeding vessels the cut edges of the mucous membrane are brought into apposition by a continuous silk suture or interrupted suture of silk-worm-gut, or such other material as the operator thinks well to employ. The patient is kept in bed for at least two weeks; her bowels are regulated, and the bladder should not be allowed to become overdistended. The sutures should be removed in about ten days."

SURGERY.

1. A *tumor* is a pathological new growth which tends to persist independently of the structures in which it lies, and which performs no physiological function.

Tumors are classified as follows:

I. Those derived from mesoblast:
(*a*) *Benign:* Lipoma, fibroma, chondroma, osteoma, myxoma, myoma, neuroma, glioma, angioma, lyphangioma.
(*b*) *Malignant:* Sarcoma.
II. Those derived from epiblast or hypoblast:
(*a*) *Benign:* Adenoma, papilloma.
(*b*) *Malignant:* Carcinoma.
III. Cystic tumors.
IV. Teratomata.

2.

	Sarcoma	Carcinoma
1. *Origin.*	Entirely mesoblastic (connective tissue type).	Epiblastic and hypoblastic. (Epithelial tissue type.)
2. *Stroma.*	Intercellular. Rarely forms alveoli.	Vascular connective tissue which surrounds and forms the walls of the alveoli; these communicate with one another, and contain masses of epithelial cells.
3. *Cells.*	Granulation tissue or embryonic connective tissue cells; shape and size vary.	Epithelial cells contained within alveoli; shape and size vary.
4. *Intercellular substance.*	May be present.	Absent, or merely fluid.
5. *Vessels*	Embryonic in character. They are in direct contact with, or may be formed by, the special cells, slightly modified, of which the tumor is composed.	Well developed; entirely contained within the connective tissue stroma, and supported by the walls of the alveoli. Seldom in contact with the cells.
6. *Spreads.*	Primarily and secondarily by blood vessels, rarely by the lymphatics.	Primarily by lymphatics, except in the later stages, when it may also spread by blood vessels, in which case it spreads with very great rapidity. Secondarily by blood vessels.

(*Cyclopedia of Medicine and Surgery.*)

Two varieties of carcinoma.—Squamous carcinoma; columnar carcinoma.

Two varieties of sarcoma.—Round-celled sarcoma; giant-celled sarcoma.

3. A *hernia* is the protrusion of a viscus from its normal situation through an opening (normal or abnormal) in the cavity in which it is contained.

Predisposing causes.—(1) Male sex; (2) age—active years of life; (3) nonobliteration of the funicular process of peritoneum; (4) late descent of the testis; (5) abnormal length of the mesentery; (6) phimosis; (7) inherited weakness of the abdominal walls; (8) general ptosis of the abdominal viscera.

Varieties of Hernia.—Hernia may be classified:

I. *Anatomically:*

1. Inguinal
   - Oblique
     - Acquired
     - Congenital
     - Infantile or encysted
   - Direct
     - External
     - Internal
   - Interstitial
     - Intraparietal
     - Interparietal
     - Extraparietal

[Incomplete, or Bubonocele.]

2. Femoral

3. Umbilical
   - Congenital
   - Of infants
   - Of adults

4. Ventral. 5. Lumbar. 6. Obturator. 7. Diaphragmatic. 8. Pudenal, etc.

II. *Clinically.*—Reducible irreducible, obstructed or incarcerated, inflamed, and strangulated.

4. The *antiseptic* plan of treating wounds has for its object the prevention of bacterial development in wounds by the use of *chemical agents*, some of which are true germicides, capable of destroying the bacteria, while others merely prevent or inhibit their growth. Among the multifarious antiseptic agents which have been used, the most prominent are carbolic acid, corrosive sublimate, biniodide of mercury, iodine, iodoform, formalin, boric acid, salicylic acid, etc.

The *aseptic* method of treating wounds consists in the elimination of chemical antiseptics as far as possible, and the substitution of heat, dry or moist, as a sterilizing agent. Every efficient antiseptic is more or less toxic and irritant and the less they are introduced into wounds the better. Of course, there are two elements which can never be sterilized apart from chemical antiseptics—*viz.*, the skin of the patient and the surgeon's and assistant's hands—and thus the most complete aseptic precautions can never entirely eliminate chemical agents."—(From Rose and Carless' *Surgery.*)

5. *Operation for complete fistula in ano.*—This consists in "the conversion of the fistula into an open wound so that it may heal from the bottom. A grooved director is passed through the fistula into the rectum, and the overlying tissues severed with a bistoury. The sphincter should never be cut more than once, because of the danger of incontinence. All branching sinuses likewise should be opened, and all fibrous tissue, with undermined skin, cut away with scissors. The bleeding is then checked, and the wound packed with iodoform gauze. If the fistula is lined with mucous membrane it must be completely excised. A blind external fistula may be excised and the wound sutured. A blind internal fistula may be converted into a complete one and treated as above. The bowels are confined for the first three or four days, and the wound dressed after each defecation, being irrigated with creolin and repacked with iodoform gauze." (Stewart's *Surgery.*)

6. *Gallstones.*—"While the calculus remains free in the gall-bladder, usually there are no symptoms. Impaction of the stone in the common duct gives rise to intermittent jaundice, following sharp pain in the right hypochondriac or epigastric region, frequently radiating toward the right scapula, nausea, vomiting, sweating, depression, and often intermittent fever (Charcot's intermittent fever). When the stone is impacted in the cystic duct, jaundice is less common, but the hepatic colic is severe, and dropsy of the gall-bladder may occur. The diagnostic points are the age, sex, history of previous attack, with jaundice and intermittent fever, location of the pain, dark, amber-colored urine, containing bile, and sometimes the finding of the stone in the feces.

Surgical treatment.—Cholecystotomy is done through an incision parallel to and 1½ inches below the costal margin over the gall-bladder. The liver is drawn up and the intestines packed away with gauze. If the gall-bladder is distended the fluid is removed by tapping it with a trocar and cannula. The opening is then enlarged, and the stones are removed with a scoop. The bile-ducts are examined along their whole course by a finger externally, and by a long probe internally. If the interior is fairly healthy, the opening is sutured with two layers of continuous sutures and the abdomen is closed. Usually it is necessary to drain the gall-bladder for a time, in which case the margins of the opening are stitched to the peritoneum and transversalis fascia of the abdominal wound. The fistula thus established soon closes if there is no obstruction to the passage of the bile into the intestine. If not, it must be closed by a plastic operation or cholecystenterostomy."—(*Aids to Surgery.*)

7. In *fracture of the surgical neck of the humerus*, the head of the humerus will be found in the glenoid cavity, but it will not rotate with the shaft; the arm will appear shorter; and crepitus and abnormal mobility will be elicited unless there is impaction.

In *dislocation of the shoulder joint*, the glenoid cavity will be empty, and the head of the bone will be found in an abnormal position; the arm will appear longer; there will be no crepitus, and no abnormal mobility.

8. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downwards from behind. The lower fragment is driven backward and upward, and rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip

of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture. *Treatment:* Disimpaction and reduction are brought about by grasping the hand by the "shaking-hands" grip, extending and adducting the hand and lower fragment. The arm is then fixed on a splint. It is very important in this fracture to start massage and passive movement not later than the end of the first week, to prevent stiffness. Union is firm in three weeks.—(*Aids to Surgery.*)

9. A *dislocation* is a condition in which the ends of the bones which enter into the formation of a joint are displaced. *Two exciting causes* are: External violence and muscular force.

10. SEPTICEMIA. "The *symptoms* may be noticed a few hours after a wound, or not for several days. There is usually a chill, with a rapid rise in temperature to 104° or 105° F.; the fever persists, being less in the morning and greater in the evening; in many cases there are violent chills at irregular periods, followed by high temperature and drenching sweats. The pulse increases in rapidity and decreases in tension. In severe cases the pulse rate reaches 150 or more, finally becoming so rapid and weak that it cannot be counted. There is often marked depression of the nervous system, the patient being stupid and quiet (typhoid state); or delirium, restlessness, picking at the bed clothes and twitching of the tendons; in either case coma precedes death. Although the respirations are quickened, signs of imperfect oxygenation of the blood are often seen in the face, which may be cyanotic. The tongue is dry, coated, red at the edges, pointed at the tip, and sordes are present upon its dorsum and upon the lips. There are loss of appetite, occasionally vomiting, often diarrhea. Petechiæ may appear in the skin and mucous membranes, and, owing to the disintegration of red blood cells, hematogenous jaundice may develop. The skin may present eruptions also in the form of vesicles or pustules, or simulating urticaria, measles, or scarlet fever. The urine is scanty, high colored, and contains albumin, toxins, and frequently bacteria; the spleen and often the liver are enlarged, and there may be leukocytosis. Bacteria may be discovered in the blood by cultural methods. The *local manifestations* vary from slight inflammation to the graver forms of cellulitis and are not always characteristic, although in many cases the wound discharges a thin pus, while the activity of the lymphatic vessels is shown by red lines of lymphangitis running to the nearest lymph glands, which are swollen and tender, or even suppurating. The veins about a suppurating wound may become inflamed, and blocked with coagulated blood (thrombophlebitis). Bacteria may invade and soften this thrombus, portions of which may be washed into the blood stream as emboli."—(Stewart's *Surgery.*)

Treatment of Senile Debility.—Many men between sixty-five and seventy have well preserved vital organs and good appetite and digestion, yet have small physical and mental vigor and tire easily. The mental state is apt to be one of depression and discouragement. Some of these patients will later show cerebral softening, while in others the disturbance is functional and due to diminished endocrinic activity. The best drug for these subjects is some form of phosphorus, preferably the glycerophosphate of magnesia. The diet should be restricted to the calory requirements. The writer believes in the formation of an issue on the shoulder to avert the probable cerebral hemorrhage in the organic form of debility, and he seems not to regard it necessary to caution against any danger of sloughing of the skin.—*Il Policlinico.*

Miscellany

Emigration to Morocco.—Europe has not "gone dry" and Morocco is not "wet," yet there is such a concerted movement from the Mediterranean countries of Europe to Morocco that authorities are seeking the motive. Even during the war the movement was active. In Casablanca, the chief port, there are now 44,000 indigenous inhabitants inclusive of 8,000 Jews, with 22,000 French, 9,000 Italians, and 9,000 Spanish, not to mention small colonies of Portuguese, Greeks and Britons. The word "French" here, is however, misleading for it comprises many Algerians and Tunisians who are in reality Jews or Italians or Spanish. Rabat, another city, also contains a very mixed population of Europeans. The British population of Morocco cities is also deceptive for it comes from Malta and other Mediterranean localities and the people are really Arabs, Spanish, etc. The migration to these African cities can hardly be due to climatic considerations, for on the coast the weather is very humid throughout the year and torrid in the summer. In the interior the climate is quite different and there are mountains which are from 3,000 to 12,000 feet above sea level where with hot summers the winters may be delightful and even cold. There is no doubt that with peace and under the protection of France the mountains and high ground of Morocco will come into extensive use for winter resorts and sanatoria. There are already tuberculosis sanatoria at an altitude of 4,500 feet. Beautiful forests of cedar will add to the popularity of the winter resorts. For permanent residence, however, it does not appear that the climate will suit French migrants by reason of the hot summers, the humidity of the litoral, and other drawbacks.—*La Presse Médicale.*

Death of Engstrom.—Otto Engstrom, the well-known Scandinavian gynecologist, recently died suddenly and his obituary appeared in the *Finska Läkaresällskapets Handlingar* for November-December, 1919, lxi, 11-12. He was born in Sweden, in 1853, and took his degree at Stockholm in 1876. He did not undertake any foreign post-graduate studies until 1882, when he took courses under Schroeder, Winckel, and Martin, in obstetrics and gynecology. After some years in Stockholm he was offered the chair of his specialties at Upsala, in 1890, and the same chair at Lund, in 1901. In 1897 he acquired international prominence by the annual publication in German of his "Mittheilungen," to which he personally contributed one hundred and twenty-five articles. This was followed by membership in the Deutsche Gesellschaft für Gynäkologie and the Società Italiana di Ostetricia e Ginecologia. He was noted for his regular attendance at the various International Congresses and was active in the Norse Surgical Society, which is a sort of Pan-Scandinavian body of surgeons. The date at which he assumed the chair of obstetrics and gynecology at Helsingfors is not stated; apparently he had received the unusual distinction of a professorship in all four of the Swedish universities. He was honored by two "Festschrifts" on the occasions respectively of his fiftieth and sixtieth birthdays.

OLIVER WENDELL HOLMES AND THE MEDICAL STUDENT.*

BY KARL M. VOGEL, M.D.

NEW YORK.

IT is suggestive that the ancients represented Apollo, the tutelary deity of our profession, as bearing in his hand the lyre, to show that he was also the patron of the arts of song, and made him the friend and close associate of the muses. It need not surprise us therefore to find that many of the sons of Aesculapius have done homage to the god of healing in his dual capacity, and while laying their garlands before his shrine, have not disdained also to woo the difficult favors of the sisters nine, so that the scrolls of literature record the names of not a few of our brethren whose pens have earned for them enduring fame. Rabelais, the robust humorist-philosopher; Fracastorius, syphilographer and poet; Linacre, the scholar and humanist; Sir Thomas Browne, the moralist and mystic; John Locke, philosopher and philanthropist; Goldsmith, the Beloved Vagabond of literature; Keats, cut off untimely "before his pen had gleaned his teeming brain; Crabbe, the singer of rural lays; Smollett, the scapegrace hero of his own picturesque romances; Eugène Sue, the aristocrat fallen upon evil days; John Brown of Edinburgh, friend of Marjorie Fleming and his own immortal Rab, down to the beloved Weir Mitchell and Sir William Osler of our own times—the list is a long one of our colleagues who through the centuries have sharpened the quill with the scalpel, and have written pages that have endured though their prescriptions are forgotten. Not all, indeed, of them have touched the heights, and some of them, soon forsaking the practice of their profession showed but little of its influence in their writings, but we are glad to number them as initiates in our mysteries. Of all of these and of their fellows whom I have not named, none has a greater claim on the affections and esteem of medical men than Oliver Wendell Holmes. Throughout all his long life his connection with medicine was intimate and fruitful and his professional work alone is sufficient to command our admiration, while his other writings through their sparkling wit and gentle humor, and their keen appreciation and kindly tolerance of the foibles and weaknesses of his fellows have charmed and delighted countless readers. The example he has given as a student and teacher of medicine, and as a student and recorder of the lights and shadows of life is so inspiring and instructive that no medical man, and especially no young practitioner, should be unfamiliar with the story of his work. No one has shown more clearly than he that scientific writing need not necessarily be dull reading, and that a truth is no less convincing for being gracefully expressed.

In his student days at Harvard in the "famous class of 1829," as it used to be called, Holmes already showed the charm of personality and grace of mind for which he has always been remembered. He held a leading place in the social life of his class and was often called upon to contribute verses on suitable occasions, while the odes he regularly wrote for the class reunions have been considered some of his best work. Some of these early writings were printed, including the stirring "Old Ironsides," which is to be found in most school readers, and this led him afterward to say that "there is no form of lead poisoning which more rapidly and thoroughly pervades the blood and bone and marrow than that which reaches the young author through the mental contact with type metal." At this time he described himself as "a plumeless biped of exactly five feet three, when standing in a pair of substantial shoes, having eyes which I call blue. I am rather lazy than otherwise and certainly do not study as hard as I ought to. I am not dissipated and I am not sedate. I stand at the humble rank of seventeenth scholar." After graduation he studied law for a year, but soon found the toga less appealing than the lancet, and entered the Harvard Medical School at twenty-one. Three years later he arrived in Paris, eager to acquire the finish of continental study, at that time deemed absolutely essential to a proper medical education. Paris had then displaced the supremacy of London and Edinburgh as the favorite post-graduate schools for medical men, in its turn a generation later to be succeeded by the lure of the German and Austrian universities. A fourth era in the trend of medical education is perhaps now dawning, and we may yet see the current setting toward instead of away from our native shores. Young Oliver found congenial fellow students sharing his period of foreign education—young men whose names have become well known in the annals of American medicine. Jackson, Bigelow, Hooper, Warren, Gerhardt, Morse, Shattuck, Stillé, were all his intimates and worked and played by his side. He lived in the Latin Quarter, and at once threw himself into the spirit of a life as different

*Read before the Nu Sigma Nu Fraternity, October 15, 1919.

as possible from the staid New England surroundings in which he had grown up. His letters home are filled with vivacious and enthusiastic accounts of his experiences, and his delight in the scenes he witnessed in the hospitals, streets, and theaters. He describes his day as beginning at seven in the wards of La Pitié, where he attended lectures and clinics until eleven, when he breakfasted. He studied until five, and then dined at some café in company with his fellow students. The Parisian cooking won his warm approval, and he comments on the food as being "so different from the crude joints, the massive puddings, the depressing pies, and the hard cider which marvelously nourished New England in its era of development."

The spirit of the times was such as to fill a young student with enthusiasm. It was a period of transition when the serpents of the caduceus were sloughing their dusty skins of the old polemical, disputatious days, and emerging in the brighter colors of exact clinical observation. Bichat had already led the way by his epoch making insistence on the autopsy table as the correct means of verifying diagnoses and studying the manifestations of disease, instead of the endless abstract discussions which till then had so befogged the understanding of morbid processes. The great Corvisart, Napoleon's physician, had preached and demonstrated the value of close clinical observation, and his no less great pupil, Laennec, had developed the art of physical examination by the invention of the stethoscope and the application of Auenbrugger's principles of percussion, which till then had received scant attention. Louis, the teacher with whom Holmes came in closest contact, placed the study of disease on a firmer basis by emphasizing the value of statistical reports, in which deductions were drawn not from single patients, but from whole series of similar cases. In his farewell address to the Medical School of Harvard Holmes speaks of some of his teachers at this time. Louis, whom he especially admired, he says was the object of the reverence, almost the idolatry, of his students. He made rounds with Larrey, Napoleon's favorite surgeon, who was still strong and sturdy, and he was thrilled by the eloquence of Dupuytren. Broussais he compares to "an old volcano which has pretty nearly used up its fire and brimstone, but still bubbling and boiling in its exterior." Piorry, percussionist and poet, he terms "expert alike in the resonances of the thoracic cavity, and those of the rhyming vocabulary." Velpeau, Andral, Trousseau, and Alibert were others of the great men of the time who were favorites of the American students. For Lisfranc he cared less, saying of him, "he was a great drawer of blood and hewer of members. I remember his ordering a wholesale bleeding of his patients, whatever might be the matter with them, one morning when a phlebotomising fit was on him. I recollect his regretting the splendid guardsmen of the old Empire, for what? because they had such splendid thighs to amputate." Ricord, the genito-urinary surgeon, he calls the "Voltaire of pelvic literature —a sceptic as to the morality of the race in general, who would have submitted Diana to treatment with his universal specifics and ordered course of blue pills for the vestal virgins."

He recounts with delight how he and a frien would each day go to the morgue as if marketin for the day's provisions and for fifty sous apiec get a body on which to practice operative surger and which by night they would have slashed t bits. All in all he must have had a splendid tim both at work and play, and when the time for hi return arrived he pleaded with his father for fu ther funds to prolong his stay, reminding him i an ardent letter that "a boy is worth his manur as well as a potato patch."

On his return to Boston he started in practic and was moderately, but not unusually successful Perhaps the staid New Englanders were no greatly drawn to a young doctor who was know to be guilty of the offense of writing poems, an good ones to make it worse, and the Bostonia sense of humor was not equal to such witticism as his announcement of "small fevers gratefull received." At any rate he found time to carr on scientific work and between 1836 and 1837 wo three out of four Boylston prizes with his essay on "Indigenous Intermittent Fever in New England"; on "Neuralgia," and on "The Utility of Direct Exploration in Medical Practice." He was on of the first physicians in this country to make extensive use of the microscope, and also inventec a hand stereoscope which it is said would have added greatly to his revenues had he patented it After spending a year or two as Professor o Anatomy at Dartmouth, at the age of 38 he was made Professor of Anatomy, Histology, Physiology, Microscopy, and kindred subjects at Harvard In fact, his teaching duties were so numerous that he said his place on the faculty "was not a chair but a whole settee." This post he held for 3 years, though in 1871 a separate chair of Physiology was established. As might be expected, his lectures were a delight to his hearers, for he combined the skill of the sympathetic teacher, understanding the needs of the student, with the charm of the practiced raconteur, and his lecture was always the last on the day's list, for it was known that he was the only one who could hold the jaded attention of the students at that hour. His fertility in apposite comparisons was inexhaustible: in speaking of the pelvis he pointed to the pubic synchondrosis and said: "This is the triumphal arch under which every candidate for immortality has to pass." "These are the tuberosities of the ischia on which man was designed to sit and survey the works of creation." No one but Holmes could have had the whimsical conceit of comparing the infinitesimal convolutions of the sweat glands to the coils of a fairy's intestine.

A graphic picture of the conditions under which the Bob Sawyers of that day received their instruction is given by Professor Dwight, Holmes' successor in the Chair of Anatomy. "The amphitheater, the seats of which were at a steep pitch, was entered by the students from above through two doors, one on each side, each of which was approached by a steep stairway between narrow walls. The doors were not usually opened until some minutes after the hour. The space at the top of these stairs was a scene of crowding, push-

ing, scuffling, and shouting indescribable, till at last a spring shot back both bolts at once, and from each door a living avalanche poured down the steep alleys with an irresistible rush that made the looker-on hold his breath. How it happened that during many years no one was killed, or even severely injured, is incomprehensible."

The description is continued by Dr. David Cheever, Holmes' demonstrator of Anatomy, who says of the Professor that "He enters and is greeted with a mighty shout and stamp of applause. Then silence and there begins a charming hour of description, analysis, simile, anecdote, harmless pun which clothes the dry bones with poetic imagery, enlivens a hard and fatiguing day with humor, and brightens to the tired listener the details of a difficult, though interesting study. We say tired listener because, will it be believed? the student is now listening to his fifth consecutive lecture of that day, beginning at nine o'clock and ending at two; no pause, no rest, no recovery for the dazed senses, which have tried to absorb Materia Medica, Practice, Obstetrics, and Anatomy all in one morning, by five learned professors. One o'clock was always assigned to Dr. Holmes, because he alone could hold his exhausted audience's attention." It is little wonder that through the many years until he finally withdrew from active teaching in 1882 he was the idol of his students.

Of his medical essays among the best known are the two on "Homeopathy and Its Kindred Delusions," which he devoted to a trenchant analysis of the doctrines of that therapeutic fad and their refutation by the weight of his logic—a true *reductio ad absurdum*. Written with his usual vivacity, they are beautiful examples of the effectiveness of cold scientific reasoning in the demolition of vague and ill-founded principles, and illustrate admirably the application of the advice he himself received from Louis: "Formez toujours des idées nettes. Fuyez toujours les à peu près." The closing passage of the second essay is well worth quoting:

"As one humble member of a profession which for more than two thousand years has devoted itself to the pursuit of the best earthly interests of mankind, always assailed and insulted from without by such as are ignorant of its infinite perplexities and labors, always striving in unequal contest with the hundred-armed giant who walks in the noonday, and sleeps not in the midnight, yet still toiling, not merely for itself and the present moment, but for the race and the future. I have lifted my voice against this lifeless delusion, rolling its shapeless bulk into the path of a noble science it is too weak to strike, or to injure."

Of more importance, and representing a contribution to medical knowledge of such magnitude as to justify Holmes' enduring fame as a great physician as well as a great writer, is his memorable essay on "The Contagiousness of Puerperal Fever." Written at a time when obstetricians the world over were holding up their hands in helpless horror at the ravages of a pestilence which decimated the wards of lying-in hospitals, and spared the homes of the greatest as little as the hovels of the poor, its principles formulated with prophetic vision before the science of the bacteriologist had even been conceived, it is a monument more enduring than brass to its inspired propounder. Holmes relates how he was led to consider the question through the discussion at a medical meeting of the case of a physician dying of septicemia as the result of an autopsy wound received while examining the body of a patient who had succumbed to puerperal fever. The paper which was the fruit of his studies was read before the Boston Society for Medical Improvement, and printed in the *New England Quarterly Journal of Medicine and Surgery* for April, 1843—an ill-starred publication that perished within a year. The essay was separately reprinted twelve years later, under the title of "Puerperal Fever, a Private Pestilence," together with an introduction in which Holmes replied with complete absence of personalities, but with inflexible, deadly tenacity of conviction, to the storm of opposition his accusation that "The disease known as puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses" had aroused in many members of the profession who preferred to impute the deaths they had left in their wake to an inscrutable dispensation of Providence, rather than to their own negligence. Two of his most determined opponents were the Philadelphia professors Hodge and Meigs, who were loud in their denunciations of the revolutionary doctrine and inveighed against it, both in print and in their lectures. In his comments on these attacks, Holmes says that:

"To the medical students, into whose hands this Essay may fall, some words of introduction may be appropriate, and perhaps, to a small number of them, necessary. There are some among them who, from youth, or want of training, are easily bewildered and confused in any conflict of opinions into which their studies lead them. They are liable to lose sight of the main question in collateral issues, and to be run away with by suggestive speculations. They confound belief with evidence, often trusting the first because it is expressed with energy, and slighting the latter because it is calm and unimpassioned. They are not satisfied with proof; they cannot believe a point is settled so long as everybody is not silenced. They have not learned that error is got out of the minds that cherish it, as the tænia is removed from the body, one joint, or a few joints at a time, for the most part, rarely the whole evil at once. They naturally have faith in their instructors, turning to them for truth, and taking what they may choose to give them; babes in knowledge, not yet able to tell the breast from the bottle, pumping away for the milk of truth at all that offers, were it nothing better than a Professor's shrivelled forefinger."

To the personal disparagement contained in Professor Meigs' vindictive onslaught he replies:

"I take no offense, and attempt no retort. No man makes a quarrel with me over the counterpane that covers a mother, with her new-born infant at her breast. There is no epithet in the vocabulary of slight and sarcasm that can reach my personal sensibilities in such a controversy. Only just so far as a disrespectful phrase may

turn the student aside from the examination of the evidence, by discrediting or dishonoring the witness, does it call for any word of notice."

There is no time at present to discuss the substance of this medical classic, nor even to do more than mention the later work of Semmelweiss, who in Vienna and Buda-Pesth furnished the experimental evidence which definitely proved the truth of Holmes' contentions, and himself encountered opposition of unparalleled animosity, so that he finally died a broken and disappointed man. As one writer has said, "If Semmelweiss could have written like Holmes, his doctrine would have conquered Europe in a year."

The collection of Holmes' writings entitled "Medical Essays" includes numerous other papers of the greatest interest to professional readers and especially to the student. He was always opposed to the then common practice of over-drugging, or as he termed it "the prevalent idea of poisoning out diseases as one smokes out vermin." In "Currents and Countercurrents in Medical Science" he refers to this when he says:

"How could a people which has a revolution once in four years, which has contrived the Bowie-knife and the revolver, which has chewed the juice out of all the superlatives in the language in Fourth of July orations, and so used up its epithets in the rhetoric of abuse that it takes two great quarto dictionaries to supply the demand; which insists in sending out yachts and horses and boys to out-sail, out-run, out-fight, and checkmate all the rest of creation; how could such a people be content with any but 'heroic' practice? What wonder that the Stars and Stripes wave over doses of ninety grains of sulphate of quinine, and that the American eagle screams with delight to see three drachms of calomel given at a single mouthful?"

"Border Lines in Medical Science" contains arguments in favor of the more extensive use of the microscope in medical investigation, which seem self-evident to us to-day, though of great weight a couple of generations ago, and which still have power to charm by their graceful felicity of expression. "Scholastic and Bedside Teaching" includes many a lesson which it would be well for us to ponder over in these days when we are too prone to let the laboratory problems crowd out of our minds the patient's immediate ills, forgetting Hufeland's aphorism, "the physician must generalize the disease and individualize the patient." Holmes says "the bedside is always the true center of medical teaching." "We are willing to give Liebig's artificial milk when we cannot do better, but we watch the child anxiously whose wet-nurse is a chemist's pipkin. A pair of substantial mammary glands has the advantage over the two hemispheres of the most learned Professor's brain, in the art of compounding a nutritious fluid for infants."

The collection contains four more essays: "The Medical Profession in Massachusetts"; "The Young Practitioner," "Medical Libraries," and "Some of My Early Teachers," whose titles indicate the interest of their contents.

Through all the years of his professional life Holmes' other activities were no less absorbing. His fame as a lecturer on non-medical subject was great, and the list of his poetical works and what he called his "medicated novels" steadily increased. When James Russell Lowell was offered the editorship of the *Atlantic Monthly* he accepted only on condition that Holmes should be engaged as the first contributor, and for the next twelve months the reading world was delighted by the successive papers of the "Autocrat of the Breakfast Table," followed in later years by the conversations of "The Professor" and "The Poet" at the same genial board.

So great was the worth of his contributions to medicine as author and educator, so compelling the charm of his writings as poet, novelist, and essayist, that posterity is still undecided in which field he deserves most honor. His own difficulty in determining which laurel wreath he prized more highly is shown by his reply to Sir William Osler who asked him from which he derived the greatest satisfaction, the essay on puerperal fever which had probably saved more lives than any individual gynecologist, or "The Chambered Nautilus," which had given pleasure to so many thousands. To this question he replied:

"I have rarely been more pleased than by your allusion to an old paper of mine. There was a time certainly in which I would have said that the best page of my record was that in which I had fought my battle for the poor poisoned women. I am reminded of that essay from time to time, but it was published in a periodical which died after one year's life, and therefore escaped the wider notice it would have found if printed in the *American Journal of the Medical Sciences*. A lecturer at one of the great London hospitals referred to it the other day and coupled it with some fine phrases about myself which made me blush, either with modesty or vanity, I forget which.

"I think I will not answer the question you put me. I think oftenest of the Chambered Nautilus, which is a favorite poem of mine, though I wrote it myself. The essay only comes up at long intervals. The poem repeats itself in my memory, and is very often spoken of by my correspondents in terms of more than ordinary praise. I had a savage pleasure, I confess, in handling those two professors—learned men both of them, skilful experts, but babies, as it seemed to me, in their capacity of reasoning and arguing. But in writing the poem I was filled with a better feeling—the highest state of mental exaltation and the most crystalline clairvoyance, as it seemed to me, that had ever been granted to me—I mean that lucid vision of one's thought and all forms of expression which will be at once precise and musical, which is the poet's special gift, however large or small in amount or value. There is more selfish pleasure to be had out of the poem—perhaps a nobler satisfaction from the life-saving labor."

All of this is old to many readers, yet I think that those who know Holmes' writings best are likely to be the ones who will be most pleased to have had his work and personality recalled to them. For the others who are not yet his disciples I most warmly urge speedy acquaintanceship with the pages of one who so often wrote especially for medical students, whose heart was so much in his

teaching that he once said "After every lecture you feel that something has gone from you," and of whom Osler said that he was "the most successful combination the world has ever seen of the physician and the man of letters."

680 Madison Avenue.

THE ANTITUBERCULOSIS MOVEMENT IN THE UNITED STATES PRIOR TO AND SINCE THE FORMATION OF THE NATIONAL TUBERCULOSIS ASSOCIATION.

WITH BRIEF TRIBUTES TO ITS DEPARTED LEADERS.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

The following is a preliminary report on the history of the National Tuberculosis Association, comprising its fifteen years' activity from its first annual meeting in 1905 to that held April 22 to 24, 1920, at St. Louis, Mo.

In order fully to appreciate the fifteen years of activity of our association it is necessary to study the history of the antituberculosis movement in the United States not only since but also prior to the formation of the organization. The first systematic attempt to study the causes and prevention of tuberculosis in the United States was made by Dr. Henry Ingersoll Bowditch between the years 1850 and 1860. He was then busily engaged in correspondence with medical men throughout New England to determine if possible factors which favored the production of pulmonary diseases. Dr. Bowditch was particularly anxious to determine the relation of soil moisture to the prevalence of pulmonary tuberculosis.

The first authentic record of the use of the open-air treatment for tuberculosis in the United States dates back to about 1808, when Nathaniel Bowditch, the celebrated mathematician, father of the just mentioned physician, Henry Ingersoll Bowditch, and grandfather of Dr. Vincent Y. Bowditch of Boston, treated himself by that then unique method. Professor Nathaniel Bowditch, having had a hemorrhage with evident signs of tuberculosis at the age of thirty-five, succeeded in arresting the disease by a prolonged journey with horse and buggy, living and sleeping in the open air.

The first institution devoted to the exclusive treatment of the consumptive poor in all stages of the disease was established in Boston in 1857. It was called the Channing Home, named after the celebrated Unitarian divine. The first private sanatorium for the treatment of the tuberculous was established in Asheville, N. C., in 1875, by Dr. Joseph W. Gleitsmann. The first sanatorium for the poor and those of moderate means was founded by Dr. Edward L. Trudeau at Saranac Lake in 1884, under the name of "Adirondack Cottage Sanitarium." The first sanatorium established near a large city without regard to climatic advantages was the Sharon Sanatorium, near Boston. It was opened in 1890, and owes its existence to the enthusiasm and personal work of Dr. Vincent Y. Bowditch.

In 1893 a voluntary notification of private cases of tuberculosis was inaugurated by the New York City Health Department. The first State sanatorium for tuberculosis was established by an act of the State Legislature of Massachusetts in 1895; it is located at Rutland, Mass., and was opened for the reception of patients in October, 1898.

The first municipal hospital for the consumptive poor in the United States was established on Blackwell's Island, New York City, in 1902, by the Department of Charities, under the direction of Mr. Homer Folks, and is known as the Metropolitan Hospital. In 1903 the Stony Wold Sanatorium for tuberculous working women and tuberculous children was established at Lake Kushaqua, N. Y. This institution owes its inception to the thoughtful wives of two New York physicians —Mrs. James E. Newcomb and Mrs. George F. Shrady. The first seaside sanatorium for tuberculous and scrofulous children was established in 1904 at Coney Island by the A. I. C. P.

The first dispensary class in the United States devoted exclusively to the treatment of tuberculosis was inaugurated in 1894 by Dr. Edward J. Bermingham of New York City, at the New York Throat and Nose Hospital.

The first municipal dispensary for the treatment of the consumptive poor was established by the city of New York under the name of Clinic for Pulmonary Diseases of the Health Department. It was started mainly through the initiative of Professor Hermann M. Biggs, then General Medical Officer of the city, and was opened in March, 1904.

The first auxiliary to a tuberculosis dispensary was established in 1907 in connection with the tuberculosis clinic of the Presbyterian Hospital of New York City. It owes its existence to the enthusiasm and devotion of Mrs. J. Borden Harriman, Mrs. Straight, and Mrs. Rumsey.

The first exhibition on tuberculosis in this country was held in Baltimore in January, 1904, under the joint auspices of the Tuberculosis Commission of the Maryland State Board of Health and the Maryland Public Health Association.

The first periodical in America devoted entirely to tuberculosis was the *Journal of Tuberculosis*, which first appeared in June, 1899, under the editorship of Carl von Ruck, B.S., M.D., of Asheville, N. C. In 1903 the *Journal of the Outdoor Life* saw the light of day at Saranac Lake, N. Y., under the able leadership of Dr. Lawrason Brown. This journal has been productive of a great deal of good and has now no less than 6,500 readers.

The first endowed institution for the study, treatment, and prevention of tuberculosis was founded in Philadelphia, Pa., in 1903. It owes its existence to the well-known philanthropist, Mr. Henry Phipps of New York. This institute is now a part of the University of Pennsylvania.

The first tuberculosis society in the United States was formed by Dr. Lawrence F. Flick of Philadelphia in 1892, under the name of Pennsylvania Society for the Prevention of Tuberculosis.

The first day and night camp was established in Buffalo, N. Y., July 1, 1908, under the direction of Dr. John H. Pryor, who was also the founder of

*Read before the General Meeting of the National Tuberculosis Association in St. Louis, April 22, 1920.

the second antituberculosis association in the United States in 1892.

The first tuberculosis committee working under the auspices and in conjunction with a charity organization society was founded in New York in 1902.

In 1908, after a meeting at the tuberculosis exhibition in New York, to which all the employees of the Metropolitan Life Insurance Company had been invited, the officers of the company decided to establish a sanatorium for its consumptive employees. After some litigation concerning the right of such a company to do this, permission was granted by the courts and a magnificent institution was erected at Mount MacGregor, N. Y. It was inaugurated on June 20, 1914.

In 1908 the New York Post-Graduate Medical School created the first chair of phthisiotherapy, and in 1917 the Trudeau School of Tuberculosis, named in honor of Edward Livingston Trudeau, was founded at Saranac Lake, N. Y.

The formation of the National Tuberculosis Association had its beginning during a meeting in Baltimore on January 28, 1904, at the time of the first tuberculosis exhibit. The outcome of this meeting was a most happy one. An organization was founded under the name of "National Association for the Study and Prevention of Tuberculosis." This name, suggested by Dr. Lawrence F. Flick, was chosen so as to make it distinctive from the other organizations in the field. Only recently, after the passing away of Mr. Clark Bell and with him of all that was left of his former organization, was the much more simple name of "National Tuberculosis Association" adopted. A committee was appointed to draw up a constitution and by-laws. This constitution and by-laws were adopted on Monday, June 6, 1904, at Atlantic City. The objects of the new society are stated to be: (1) the study of tuberculosis in all its forms and relations; (2) the dissemination of knowledge about the causes, treatment, and prevention of tuberculosis; (3) the encouragement of the prevention and scientific treatment of tuberculosis. The first to hold office in the association were as follows: Dr. Edward L. Trudeau of Saranac Lake, N. Y., president; Dr. William Osler of Baltimore, and Dr. Hermann M. Biggs of New York, vice-presidents; Dr. George M. Sternberg of Washington, D. C., treasurer; Dr. Henry Barton Jacobs of Baltimore, secretary.

The gradual growth of the society, the biographies of all its officers, with their portraits and a list of their contributions on the subject of tuberculosis, the achievements of the society from year to year, and the papers read at each section, all will be enumerated in detail in chronological order in the history. In this summary I will briefly mention the most essential achievements and labors of the society.

In 1904 the association started with a membership of 26; to-day we have 25 life members and over 4,200 regular members. Prior to June, 1904, there were in the United States 23 tuberculosis associations and committees, to-day there are no less than 1,000 associations.

Prior to the organization of our association, there were in the United States 96 sanatoria and special hospitals, 24 tuberculosis dispensaries, n open-air schools, no preventoria. There are no 600 sanatoria, special hospitals and camps; 54 tuberculosis dispensaries; 3,000 open-air schoo and fresh-air classes, and 15 preventoria. In 190 there existed no tuberculosis nurses, to-day w have about 3,500 specially trained tuberculosi nurses.

Among the other outstanding features of th work of the association we may mention its organ izing and conducting the Sixth International Con gress on Tuberculosis in 1908. It started travelin tuberculosis exhibits; inaugurated the Tubercu losis Sunday, which has since developed int Tuberculosis Week; promoted the Red Cross Sea sale, which grew from a limited sale of less than 1 million in 1905 to over 400 million seals in 1919 During 1918 the National Association discon tinued its plans for Red Cross Christmas seals and in lieu of this campaign and in order to per petuate the work the Red Cross made a direc appropriation of $2,500,000 for distribution to it allied agencies. The association printed and dis tributed educational leaflets, posters, and booklet on tuberculosis, aggregating several millio copies; established the *American Review o Tuberculosis*, now having a circulation of 1,200 it published a number of research studies, such as "The Influence of Sanatoria on Surrounding Property," "Fresh Air and How to Use It," "Tuberculosis Hospital and Sanatorium Construction," etc.

Thanks to the magnificent gift of $100,000 from the Metropolitan Life Insurance Company, the association was able to establish in 1916 the Framingham Community Health and Tuberculosis Demonstration.

The National Tuberculosis Association conducted 15 annual meetings, at which no less than 560 papers on the medical and social phases of tuberculosis have been read and discussed and 15 presidential addresses delivered. In 1915 it started a series of sectional conferences which have since been conducted annually with most satisfactory results.

During the world war the association put into effect a program which had for its purpose the following up of every case of tuberculosis discharged from military camps, and a complete system of education in all of the large army camps and cantonments in the United States and France, including a special exhibit, motion pictures, lectures, and distribution of literature.

To whom are the medical profession and the people of the United States indebted for this enormous and wonderful work, amounting to the reduction of the death rate of tuberculosis from 200.7 per 100,000 population in 1904 to 140.0 in 1919? To our leaders in this work, of whom fortunately the majority are still with us. I mention first our only surviving honorary vice-president, Col. George E. Bushnell; then Hermann M. Biggs, who graced the presidential chair for two years; Frank Billings, Vincent Y. Bowditch, William H. Welch, Mazyck P. Ravenel, Homer Folks, George M. Kober, Edward R. Baldwin, Charles L. Minor, David R. Lyman, and our present honored president, Victor C. Vaughan. Our secretary, Henry

Barton Jacobs, has served the association from the beginning in 1904. William R. Baldwin, our retired treasurer; Mr. Henry B. Platt, our present treasurer; Livingston Farrand, our first executive secretary, who served the association so ably from 1905 to 1914; our present managing director, Charles J. Hatfield; Philip P. Jacobs, the assistant secretary since the year 1908; Donald B. Armstrong, the executive officer of the Community Health and Tuberculosis Demonstration, and their numerous assistants and clerical staff, comprising about 60 people.

I believe it to be apropos at this moment to recall in reverence and in gratitude the names of our departed leaders: Grover Cleveland, honorary vice-president from 1905 to 1908; Theodore Roosevelt, honorary vice-president from 1905 to 1919, and president of the International Tuberculosis Congress in 1908. Both of these men occupied, each for two terms, the highest office which can be conferred upon American citizens, and both of them left an imprint upon the history of the United States as ideal servants of an ideal republic, and showed us our duties to ideal citizenship. Both Mr. Cleveland and Mr. Roosevelt were deeply interested in all public health problems, and particularly in tuberculosis. Well may we be proud to count them among our numbers.

The first president of our association, our own Edward Livingston Trudeau, will always be gratefully remembered not only by us but by the American people at large for his pioneer work in the treatment of tuberculosis and his humanitarian efforts.

The next great loss our ranks sustained was in the death of Edward G. Janeway, the celebrated diagnostician, who never claimed to be a tuberculosis specialist, though there could hardly be anyone aspiring to this title who has done more for the antituberculosis cause in general, and particularly in the combat of phthisiophobia, for the individual patient or pupil as a teacher, physician, and friend.

Theodore B. Sachs, whom we may justly call the martyr president, gave up his life while in full vigor and strength because he could not endure the low attempts directed against his honor and reputation. For his memorial tablet at the Naperville Sanatorium, where his body was interred, the blind physician, Dr. Robert H. Babcock, wrote the following impressive words:

"In memory of Dr. Theodore B. Sachs, whose life was spent in disinterested efforts to relieve the condition of the unfortunate, never indifferent to the distress of others, he labored unselfishly and untiringly in their behalf, and this sanatorium, in which ground he sleeps, is a monument to his unusual greatness of heart and singleness of purpose. He loved his neighbor as himself, and was in truth a good Samaritan."

John Henry Lowman, gentle, kind, scholarly, and devoted to the highest ideals, served as sixth president of the National Tuberculosis Association from 1913 to 1914. His charming qualities and fine traits of mind and heart will long be remembered by the members of this association. Dr. Lowman's death was typical of his life. He made the supreme sacrifice as surely as any American soldier on the battlefields of Flanders and in France. When he was called to be chief of the American division of the antituberculosis work in Italy, under the auspices of the American Red Cross, already an invalid, he knew the great risk he was taking in crossing the sea, but he answered the call. He became sick on his voyage to Italy, and returned a very sick man and soon passed away. He died the soldier's death after living in the best sense of the word a physician's life.

Surgeon General George M. Sternberg served the National Tuberculosis Association as its faithful treasurer from the time of the formation of the society in 1904 to 1915. Distinguished as a soldier as well as a physician and scientist, after his retirement from the army he took the greatest interest in the betterment of the health of the capital of our country and in the housing problem of the poor. He died November 3, 1915, at the ripe old age of 78, and will long be remembered as a man of highest scientific attainments, an efficient officer, ideal citizen, and philanthropist.

On all the great souls thus far mentioned as having gone to their reward, appropriate eulogies were pronounced at the time of their passing beyond, and resolutions passed by the association which were placed on record in the transactions. Only for one have we not yet been able to do this; the great William Osler, the first physician to receive the distinction of unanimous election as honorary vice-president of the National Tuberculosis Association. He passed away only recently, and while I have no doubt that appropriate resolutions will be passed, may I be permitted to pay a brief tribute here to the man to whom our association and the medical profession of this and all civilized countries owe so much?

Sir William Osler was one of the prime movers in the formation of our society, and his interest in the tuberculosis problem in its social as well as its medical aspects has been unabated. He was closely identified with the antituberculosis movement in America as well as in England, and his counsel was sought as an expert in all that appertains to this most widespread of diseases. He added some fifty-odd important contributions to the modern tuberculosis literature. To Dr. Osler is due the formation of the Laennec Society for the Study of Tuberculosis, which is a part of Johns Hopkins Medical School, and in 1900 he established the first social service division in connection with the tuberculosis work of Johns Hopkins Hospital. The honors bestowed upon Sir William have been enumerated in the many eulogies already published, and I need not recount them here. I will only mention the two most important. Shortly after his arrival in England as regius professor at Oxford, he was created a baronet of the United Kingdom by King George V. In 1918 Sir William was made president of the British Classical Association, a rare honor indeed to be bestowed upon one whose training had been that of a physician purely and simply. Osler's interest in America, in its medical institutions, and in his countless friends and pupils was genuine and lasting until the end. His work in Oxford equalled his achievements in Montreal,

Philadelphia, and Baltimore. In answer to an inquiry prior to the publication of an article on "The Tuberculosis Situation After the World War," Sir William wrote me under date of May 26, 1919, "All goes well here and I hope we will get the tuberculosis problem settled ere long on national lines." During the war he worked for the health of the English and Allied armies. The death of his only son, Revere, who made the supreme sacrifice in the world war, was a terrible blow to this great and good man, but he bore up under it bravely. In reply to a letter of condolence from the author, after expressing his thanks with his usual warmheartedness, Sir William merely added, "It has of course been a pretty hard business." Then forgetful of his own sorrow he went on to speak of our duties as physicians in the world war. He kept on working for the soldiers and with the soldiers. He talked to them on subjects of hygiene, how to preserve their health and to prevent tuberculosis.

In November, 1919, Osler contracted pneumonia, but he himself hoped for an early recovery, and on Christmas day he sent a typically cheerful cablegram to Johns Hopkins Hospital, announcing that he was making a good fight; four days later he died. Perhaps he only sent that message to give Christmas cheer to his many friends on this side of the Atlantic. He must have realized the seriousness of his condition, for after his death the following note, dated December 23, 1919, was found among his effects: "Dear friends, the harbor is nearly reached, after a splendid voyage with such companions all the way, and my boy waiting for me." How the soul of this great man is revealed in these simple words!

Cheerfulness, an unbounded capacity for work, a devotion to the highest ideals of medicine and humanity, a marvelous scholarship, loyalty to his friends, and kindliness to the humblest of the humble, were the outstanding characteristics of Sir William Osler. His lifelong friend, Prof. William H. Welch, of Baltimore, well said of him: "To Osler nothing human was foreign. His home, both in Baltimore and Oxford, was a center of hospitality." Those who had the rare privilege to walk with Professor Osler through the medical wards or who had the good fortune to have been present at some of his receptions to students will never forget the human side of his character. Osler was devoted to his pupils, but he was also devoted to his teachers, and the veneration and enthusiasm he expressed when he spoke of his own masters and the masters of us all was an inspiration that not only stimulated the interest in historic medicine but aroused gratitude for the inheritance which the teachers of past generations have left us. On October 5, in 1905, he took the American delegation, which had attended the Fifth International Tuberculosis Congress in Paris, to the cemetery of Mont Parnasse to deposit a wreath on the tomb of Louis, the French physician, at whose feet so many American physicians of the past generation had sat. It was a touching tribute and gave the younger men a lesson in gratitude to our teachers.

Osler was one of our greatest physicians of the Anglo-Saxon race of the present day. He instructed thousands of students by word of mouth and by his writings on early diagnosis, practical prophylaxis, and rational treatment of tuberculosis. In a lecture delivered soon after his arrival in England, he said: "Probably 90 per cent. of mankind has latent tuberculosis, and if I had an instrument here with which I could look into the chest and abdomen of each of you I would probably find somewhere a small area of the disease. So widespread is the germ that practically all humans, by the time they become adult, harbor the bacillus of the disease. But we do not die, because we are not guinea-pigs and rabbits. We have attained a certain immunity. But the germ is in us, though negative, and with all of us there is the possibility of slipping into the dangerous state. But when workers have living wages, when the house becomes the home, and the nation spends on food what it now spends on drink, then there will be millions instead of thousands with practically continuous immunity. For the enemy has been tracked to its stronghold, which is defended by three allies—poverty, bad housing, and drink." He looked upon tuberculosis as a disease of the masses, and particularly of those of little or no means, and we know that he induced many of his wealthy friends and patients to consecrate some of their fortunes to the relief of the consumptive poor.

Characteristic of William Osler and his labors are the words which grace the photograph he presented to those who bade him farewell on May 2, 1905, when he was about to leave for Oxford. They were the immortal words of Abou ben Adhem, "Write me as one that loves his fellow man."

16 West Ninety-fifth Street.

CONCERNING RHEUMATIC AND SOME OTHER INFECTIONS,

WITH ILLUSTRATIVE CASES.

By SAMUEL E. EARP, M.S., M.D.,

INDIANAPOLIS, IND.

PROFESSOR OF CLINICAL MEDICINE, INDIANA UNIVERSITY SCHOOL OF MEDICINE.

PERHAPS there is an inclination to give credence to the general impression that the term rheumatism is a misnomer. There has been a tendency to blanket certain symptoms under this term because the etiology in many instances seems obscure and because there is pain in some joint or muscle. If it be the knee-joint, if the condition be characterized by swelling, pain, fever and the tendency to shift from one of the larger joints to another, with possibly some evidence of a history of recurrence, shall the diagnostician offer an apology for using the term rheumatism to express this train of symptoms? Our fault has been in a lack of detail work in making a study of our patients. If there is a swollen joint with pain it has been very easy indeed to use the term rheumatism as a mantle, as we formerly used the term malaria. To say that what we call rheumatism is simply the result of some infectious process is not sufficient excuse for the abandonment of the term rheumatism; on the contrary it adds to the complexity. We surely have

certain manifestations of disease, with an approach to identity but sometimes atypical, that will not permit a banishment of the term. We must not condemn those high in authority who still claim that rheumatism is an acute infectious disease. If this be accepted, with the help of the clinical laboratory, we can easily outline the etiology of at least six types. If we must abandon the term, then we must blue pencil the leaves of any modern text-book; and why do Osler, Anders and others make this necessary, simply because we know of no other term to describe certain manifestations of disease? Shall we abandon the views of the authors who furnish a text for the medical student—are such books obsolete? Shall we say that our observations at the bedside clinic are cloaked in ignorance? Are we poorly trained, and are we teaching others fallacious doctrine? Shall we put a negative on certain factors which are alleged to represent rheumatic fever? Among such factors are: probably due to *Micrococcus rheumaticus*, large joints affected with pain and swelling; sometimes muscles elsewhere affected; fever; tendency to leave one joint and seek another; sheaths inflamed; possibly heart lesions; certain etiology; predisposing causes; general symptomatology; condition of skin and renal symptoms; pulmonary, muscular, and nervous symptoms—it is needless to go further. Until these are abandoned we must still use the name rheumatism, even though we be a "doubting Thomas."

If we retain the term, let us first look carefully for some infectious process before making a diagnosis of rheumatic fever. If there be pain in the shoulder, is there a tuberculous lung, or is the oral cavity at fault? If in the hip, let us think of an infectious process in the appendix, kidney, bladder, ovary, uterine cavity, or rectum. These are but a few instances. It is not necessary that a joint infection be caused by a nearby organ. Any portion of the body, from the occipital region to the phalanx of the great toe, may be affected in consequence of pus, for example, in the appendiceal region.

It is very true that there is much for us to learn and it is also true that we have unlearned some things. The infectious field is a large one, and when at sea we are always in deep water. I will submit a few cases from my bedside clinic notebook, which contains a résumé of my work at the Indianapolis City Hospital. They will not be given in complete form, and I will omit many of the details:

Case I.—J. B. Male. White, Age 55. *Family History.*—Mother died of heart disease, one sister died of diphtheria and one of cerebral-spinal meningitis. No tuberculosis or cancer. *Past History.*—Occupation, clerk; drank alcoholics occasionally. Had infectious diseases of childhood, and tonsillitis. Has had gonorrhea several times. Had herpes or chancre 20 years ago, but no evidence in later years to confirm it. Patient states that he had rheumatism ten years ago. *Present Illness.*—Aching pain in both knees for three days before coming to hospital. Pain first sharp, then keen and severe; much swelling and redness. After a few days of treatment pain left knees, swelling reduced; right shoulder and small finger of left hand then became involved. Next the left shoulder and arm. *Physical Examination.*—Anemic. Skin muddy. Puffiness under eyes. Pupils dilated. Coordination poor. Teeth bad; evidence of pyorrhea. Some enlargement of the thyroid. Mouth-breather. Tonsils diseased. Rhomberg's sign negative. Argyll-Robertson pupil negative. Some edema of ankles. Inguinal hernia on right side. Chest negative. Temperature 100° F., sometimes subnormal. Pulse 100. Urine examination negative.

Here are the symptoms generally accepted as acute rheumatic fever. The patient left the hospital, had a relapse and returned. Recovered in three weeks. He was given 30 grains of sodium salicylate every three hours and 10 grains of acetyl-salicylic acid every 5 hours. Joints massaged with adeps and oil of wintergreen. Bowels kept free with Dorsey's magnesia mixture. No other treatment. Doses lessened as symptoms improved, and patient instructed after his return home to take 15 grains of salicylate of sodium and 5 grains of iodide of sodium for one month; to have tonsils removed, and teeth and gums treated. He refused to have this done while at the hospital. It should have been done.

Case II.—E. M. White. Female. Age 23. Married. *Family History.*—Mother had two strokes of paralysis; after last, dragged right foot. Wassermann positive. Was given salvarsan. Has had tonsillitis and rheumatism. Father a rheumatic and helpless from it. *Previous History.*—Good health during childhood. Menstruated at 10 years. Miscarried at age of 16 years. At 20 years gave birth to a child. Has had some vaginal discharge. Soreness and swelling in joints of legs and arms two years ago. Has been in skin clinic on account of eczema of hands, and gynecological clinic on account of vaginal discharge and painful urination. Tonsils removed six months ago. *Present Illness.*—For three weeks stiffness in left elbow joint, wrist and fingers. Pain later in right elbow; some swelling. Pain in right hip and knee during past few days. *Physical Examination.*—Weight, 175 pounds. Well nourished. Wears glasses. Teeth good but gums sore and bleed easily on pressure. Right arm semi-ankylosed, and left swollen and painful. Cervical and inguinal glands enlarged. Joints elsewhere tender on palpation. Chest and abdomen negative. Temperature 100° F. and pulse 88 to 90. Respiration 20. *Laboratory Findings.*—Smear from vagina reveals gonococcus. Wassermann negative. Blood Count.—Red, 6,130,000; white, 16,500; poly., 58 per cent.; small, 30.5 per cent.; large, 10 per cent.; eosin, 5 per cent.; bass, 1 per cent. A second Wassermann negative.

We have here presented almost a typical case of gonorrheal infection usually denominated gonorrheal rheumatism. It has no bearing, of course, upon the *Micrococcus rheumaticus* or other forms of infection. When even a few of these manifestations are present, if there is a complication of ankylosis, we are fairly sure that the type is gonococcal.

Case III.—L. T. White. Female. Age 55. *Past History.*—Had tonsillitis. Has been operated on for some rectal trouble; menstruates regularly every 30 days. Has had diseases of childhood. *Present Illness.*—Five weeks ago had swelling and pain in both thumbs, later the fingers, and still later knees and ankles. *Physical Examination.*—Features coarse and masculine, with considerable hair on upper lip and chin. Does not complain of vision but has cataract in right eye. Pulsation of veins of neck, very prominent during exertion, swelling in supra-sternal notch during pronounced exertion. Mouth and chest negative. Right knee and foot greatly swollen and very painful and red. Some edema of leg. Laboratory findings negative. Temperature 102° F. Pulse 100. Respiration 25. No evidence of any focal infection. It would seem that the micrococcus was responsible. There was an uneventful recovery following very large doses of bicarbonate and salicylate of sodium. When stomach was sensitive, resorted to the use of salicylate of magnesia. Bowels kept open. No meat in diet.

In such a patient if stomach does not accept sodium salicylate kindly, 40 to 60 grains may be given per rectum twice a day or intravenously in appropriate cases.

Case IV.—M. B. White. Age 20. Married. Weight, 156 pounds. *Family History.*—Negative except parents had some heart trouble. No tuberculosis nor cancer. *Past History.*—Mumps. Rheumatism since 8 years of age, lasting from six weeks to greater portion of each winter. Attacks were preceded by "colds," sore throat, and catarrh of nasal passages. Some years ago discharge from both ears. Says her rheumatism would pass from one large joint to another. Pain was keen and sharp when moving and when quiet dull and aching. Generally joints much swollen but very little redness at some of the times. Did not notice much fever. *Present Illness.*—When in the South was well. Came North and had child, cold in head, headache, and in a few days had pain in both shoulders. Complained of shortness of breath and pain in region of the heart. When admitted to hospital, temperature 101° F. Respiration 28, pulse 116. Pain in joints, dyspnea, systolic murmur at apex, and skin moist. Urine examination shows albumin and few pus cells. *Physical Examination.*—Well nourished. Dyspnea. Pain in shoulder on movement, skin moist, pulse rapid but well sustained, apex beat to left in sixth interspace. Heart hypertrophied, systolic mumur at apex and transmitted to mid-axillary line, pulmonary second sound accentuated. Some few mucous râles in left lung posterially which cleared after forced cough.

All things considered, this patient seems to have multiple secondary arthritis with cardiac complication. Pain and heart symptoms were relieved by hypodermatic injections of atropine sulphate and morphine sulphate. Both salicylate of magnesia and bicarbonate of soda were given. At times the heart needed medication and sparteine sulphate was given in one-grain doses. Bowels were kept open by saline. Light diet and avoidance of fluctuation of temperature to body. Sometimes protected by coverings, which is always a good plan. This patient made a fair recovery, there being only a faint mitral blow, which should require treatment for a long period. Care should be taken to guard against future attacks by adopting measures of prophylaxis.

We can eliminate arthritis deformans in this case on account of mildness of joint symptoms, there being no joint deformity, no Heberden's nodes, and on account of the character of the heart lesion. The fact that the disease yielded to the salicylate of sodium made a therapeutic test and was a negative for arthritis deformans. Gout rarely appears before patient is past 30 years old, and not so often in females. Generally attacks smaller joints, preferably the great toe, and quite early. The onset and absence of pain at night also makes a fair negative. We take into view acute rheumatic fever, multiple secondary arthritis, septic arthritis, etc. The symptoms may differ in only a few points. The specific etiology may be a little doubtful except in a few cases, such as gonorrhea and syphilis, and the sequelæ sometimes show a resemblance; we must then resort to laboratory help. Even though the specific organisms are found, there may be a question whether or not some local focus of infection, such as tonsillitis, otitis media, etc., may be doing the harm. The laboratory stands well in hand with us. We are now limited to acute rheumatic fever, and arthritis, acute and chronic. Recognition is here given an acute disease. The attacks in this patient have always been preceded by exposure, cold (wet feet in this instance) sore throat, irritability of the nasal passages, which are etiological factors and relate to both of the last mentioned types, if such they may be called. Between the ages of 10 and 20 years females are more prone to both than males, and yet the temperature, pulse, respiration and cardiac symptoms may be much the same. Some of the premonitory symptoms may be almost the same. The etiology may not differ much. In acute rheumatic fever, however, there is more of an abruptness in onset. In 24 hours there may be a temperature of 100° F., and one or more large joints may be swollen, red and painful. Pain may be intense. There may be inability to change posture without causing agonizing pain, drenching sweats, prostration, and other evidence of helplessness.

Multiple secondary arthritis is not so abrupt in onset, pain not so intense expect during motion of affected part, temperature not so high, and joint symptoms not so well marked as in acute rheumatic fever. Perhaps it is drawing a fine line to say the heart lesions are not quite the same. Both are prone to heart complications, but in acute rheumatic fever endocarditis quite frequently appears (in about 35 per cent.), pericarditis and myocarditis less frequently, but later on, such lesions may present in either case. Sometimes acute rheumatic fever leaves nodules attached to or a part of the tendons and fascia, which vary in size from a shot to a pea.

Case V.—L. B. Male. Colored. Age 19. Family and present history are of little moment. *Present Sickness.*—Pain below left nipple three weeks ago, then swelling of left knee; in a few days in the right knee, then in legs and ankles; especially painful tendons. Some shortness of breath during exertion. *Physical Examination.*—Head and mouth normal but some enlargement in region of thyroid. Cardiac hypertrophy; systolic murmur at apex which is transmitted to the left axilla and over left chest to left dorsal region along vertebral border of the scapula and below. At times there had been some cough and very slight expectoration, and sputum showed some streptococci. Urine negative. Temperature 100° F. to 103° F. Pulse 100. Respiration 25. The thyroid enlargement must be considered. Perhaps this shows a resemblance to acute rheumatic fever, but it is more likely to be a streptoccocic infection with the source in doubt, unless it be pulmonary, and more careful study in this case will be required.

Focal infection is far reaching in this connection, and covers a large and important field. I have had something to say recently concerning the useless extraction of teeth, because there are those who went beyond the limit of reason; but it must be recognized that periapical abscesses may be undiscovered and may be responsible for a pathologic lesion of the lung, heart, kidney, gastrointestinal tract, or in fact, any portion of the body. Earl (*Journal-Lancet*, February, 1919) sounds a keynote when he speaks of *x*-ray diagnosis, but it is most important to obtain an accurate interpretation, for I am convinced that this is one of the common sources of error. A small shadow may be deceptive as indicating a small abscess, and the antrum and nerve openings must be kept in mind. Furthermore one of the conclusions of Earl is timely—that upon those who would advise a departure from the generally accepted rule of "where there is pus evacuate," falls the burden of proof. In the light of proved bacteriological and microscopic examinations over the entire country it is a great responsibility to assume that periapical abscesses should not be removed by surgical means.

Sanford Blum (*American Journal of the Medical Sciences*, November, 1918) says we ascribe too many ailments to focal infection, and takes the position that when bacteria are injected into the cir-

ulation arthritis occurs as an incident of the induced septicemia. Pathogenic bacteria manifest a predilection for the serous and synovial membranes, morbid processes ensue and we may have a meningitis, pleuritis, endocarditis or synovitis and it is true that there may be different types. He thinks, which appears to me to be reasonable, that the power of attacking serous and synovial membranes is not limited to the streptococcus, and that the selective morbidity is due not to specified organisms but to the lowering of the power of resistance to bacterial aggression possessed by serous and synovial membranes as contrasted with muscles, bones, nervous and connective tissues.

I have always placed much stress upon the power of resistance of the individual, and this is lessened by age or otherwise we see evidence of a pathologic condition wherein an organism was present in some portion of the body waiting for the opportunity. Do we not frequently find the mouth of a doctor or of a nurse containing a large number of diphtheria organisms? No doubt each one of us has digested, if I may use this expression, many thousand tubercle bacilli, and yet that same protection which we possess gave us an individual immunity. I have very frequently quarantined nurses who had many organisms in the mouth but who never contracted the disease that these organisms represent.

So I might call attention to the influence of toxines or numerous other causes of the lowering of the bodily resistance, all of which invites certain diseases, and this simply implies that one of the most important factors for consideration in our work is preventive medicine.

LOCALIZATION OF PULMONARY LOBES BY THE *X*-RAY.*

By MAJOR KENNON DUNHAM, M.C.,

CINCINNATI, OHIO.

It is not my purpose to tire you with a great deal of anatomy that you know. It is not my purpose even to go with you over the regional anatomy of the chest so important to thoracic surgery. But since it is never safe to depend upon our knowledge of anatomy as it should be, it is my purpose to show you how I think the *x*-ray chest plate can best help in thoracic surgery.

As the points that I wish to give you cannot be well expressed in a paper unless fully illustrated, I propose to point out from a few slides certain anatomical landmarks which can be seen upon the *x*-ray plate, and so show how lesions can be accurately located before operation. The value of this method of localization will be determined by the surgeon who uses it well; its accuracy I have fully established. These important landmarks, beside the bony structure of the chest, are the lung lobes and the trunks, the trachea and the aortic arch. In this case let the last be first and we will consider the trachea and arch.

Normally the trachea lies slightly nearer the right upper lobe than the left, and nearest the right upper lobe at its bifurcation. The aortic arch is decidedly to the left. The left bronchus passes under the aortic arch with a decided curve, while the right bronchus passes down as an almost direct continuation of the trachea. The corena leans toward the left bronchus, and it is this, with the direct fall of the right bronchus, that causes foreign bodies most often to lodge in the right lung.

Now let us consider the lobes of the lung, locating the three on the right side and the two on the left largely by the distribution of the bronchi and their branches.

The bronchus to the upper right lobe is the eparterial bronchus, so named because it lies above the right pulmonary artery. It comes off the right bronchus just below the trachea. The bronchus to the middle right is given off the main stem bronchus four or five centimeters below the eparterial bronchus. Thus it is possible to make out distinctly the upper right lobe and separate it from the middle right, and the pulmonary artery can thus be accurately located before operation.

To accomplish this stereoscopic plates must be made with the proper technique. The technique consists of fuller exposure and softer tube than is best for chest examination, and which I have fully described in the *Review of Tuberculosis*, November, 1918.

The lower right lobe, as well as the lower left, are often difficult to accurately localize in the normal chest. But if one takes good plates and carefully studies them, he will first notice that a greater number of branches are given off the main stem bronchus posteriorly, and if the trunks have been carefully charted in the upper lobes, it will be deduced that the rest of the chest cavity is occupied by the lower lobes.

When I speak of charting the trunks, it may be necessary to go into some detail. The trunks are the heavy lines extending from the hilum into the lung fields like a tree. They are the increased densities which are produced upon the *x*-ray plate by the bronchi and accompanying vessels, the lymphatics and their connective tissue.

If we divide the lung fields into three zones, the hilum or root zone, the trunk or middle zone and the periphery or pleural zone, we will find that the heavy masses at the root are the hilum; the trunks extend out in all directions from this but have a very definite location, and that beyond the trunks there are many fine branches which normally do not extend to the pleura. I have named these branches near the pleura the linear markings.

It must be remembered that these branches and trunks are not the bronchus alone, but the bronchus is within or immediately borders the trunk and can be located by it. Also remember that there is always an anterior and a posterior branch to each trunk. When we study the trunks carefully we find that they have exactly the distribution which Birch-Hirschfield gives his bronchial tree.

As an example of the locating of lesions and their limits by charting the trunks, let us consider the following: Coming off the very apex of the hilum there is a trunk passing (especially on the right side) upward, parallel to the vertebral column toward the apex. This I have named the vertebral trunk, and it is interesting to note that its branches, or the linear markings of the vertebral

*Read at the second annual meeting of the American Association for Thoracic Surgery, June 9, 1919.

trunk, all lie upon the plate within the circle of the first rib. Thus a lesion limited to the apex of the upper lobe involves this area. The anterior and posterior branches of this trunk are so close together that it is impossible to separate them unless there is a definite lesion in one or the other. Physical signs of this area are heard either in the supraclavicular or suprascapular fossæ.

The first interspace trunk comes off the hilum a little lower than the vertebral trunk, and passes up and out toward the shoulder. The anterior branch comes toward the chest wall below the clavicle. Its linear markings come near the pleura behind the first interspace and extend slightly above to the first and below to the second rib. Thus a lesion limited to the anterior branch of the first interspace trunk will come to the anterior chest wall directly below the clavicle. A lesion of the posterior branch will come to the pleura just below the spine of the scapula, mostly outside the mid-scapular line. This is a very common location for unrecognized tuberculous lesions and for light-weight aspirated foreign bodies. Usually pneumonic abscess following tonsillectomy is found in the lower right, but often it is overlooked in the posterior first interspace trunk of the upper right.

The second interspace trunks are much larger and cover a greater area than the first. The dependent branches spread out over the entire base of the upper right lobe. Remember we are speaking of the right side, the left side will be described later. These trunks come off the hilum below the first interspace trunk in a horizontal line. The usual anterior and posterior branches are given off but in addition to this there is one branch which passes upward directly below the second interspace, and another which passes out and behind the third interspace. The anterior branches give off their linear markings behind the second and third interspaces entirely across the chest and extend well to the outer edge of the pectoral muscle, while the posterior branches extend into the axilla and reach the pleura of the lower lobe posteriorly.

The middle lobe trunks, as I have said, come off four or five centimeters below those to the upper lobe (the eparterial bronchus). They leave the hilum behind the fourth rib and fourth interspace. The posterior branch passes up and back toward the base of the upper lobe, and the anterior branch passes forward and down to the anterior chest wall.

If one will think of the fifth rib as marking the upper border of the lower lobe, he will easily carry a practical line in his mind which will help to visualize the lobes. Thus one correctly thinks of the upper and middle lobes as anterior lobes and the lower lobe as the posterior lobe. Certainly for accuracy this rough line needs modification as first—the incisura above the lower lobe at the chest wall is a little higher on the left than upon the right side. Second—the apices of the lower lobes extend slightly above the fifth rib near the spine. Third—the incisura reaches the diaphragm so that in front it extends below the fifth rib.

Now this description and location of the lobes with respect to the chest wall is the usual case, and if it never changed a study of the trunks would not be necessary. But lobes are not constant. In one series of lungs which I studied there was abnormal location in twenty-five per cent. of the cases. This is probably unusual but anyone who will note his autopsies carefully will be struck with the great frequency with which abnormal lobation occurs. Then the lung is a very movable organ and contractile tissue frequently dislocates the normal position of the lobes. As you all know dislocation of the thoracic viscera is a common occurrence. What I am trying to show you is that we have a means by which we can usually determine thoracic dislocation prior to operation. But to do this it is necessary to know the various trunks and their relations to the chest wall. Necessarily there are many abnormalities of the chest wall which must be considered, and with which the trunks must be compared, but if one understands the usual bony framework of the thorax, or has a good skeleton in his closet, such deformities will be easily allowed for.

Now as to the left side. The left lower lobe is very much like the right, except that it is a little longer and less broad. Thus as we know it extends a little higher and the incisura reaches the diaphragm a little more anteriorly.

To the apex of each lower lobe there go two trunks which are given off the main stem bronchus posteriorly about the level of the middle lobe trunks. They are seen upon the *x*-ray plate to leave the hilum posteriorly and to pass back and up. They are not always seen and can never be made out except upon stereoscopic plates. The hilum otherwise obscures them.

The upper of these trunks can be followed toward the fifth interspace near the spine, while the other comes to the back about the angle of the scapula to the seventh interspace or the eighth rib. When seen they are a great help in localizing lesions within the apex of the lower lobe.

The upper left lobe is very like the upper right, but has several important differences. Its bronchus is called the hyparterial bronchus, because it passes under the left pulmonary artery as well as under the arch of the aorta. Upon the plate the left bronchus can be seen to sweep in a large curve toward the lung fields, and the vertebral trunks do not pass up so nearly parallel to the spine, but curve to the apex. Nevertheless, the linear markings come to the surface almost exactly as upon the right side. This applies to the first and second interspace trunks as well.

Next there is the linguala or lingual tip which has its own trunk and by some is compared to the middle right lobe. The bronchus to the lingual tip of the upper left comes off the hyparterial bronchus and not off the main stem bronchus as does that of the middle right lobe. The hyparterial bronchus comes off the left bronchus much nearer the branches of the right side. There is about three centimetres between them as against four or five centimetres on the right side. The lingual tip trunk is seen to leave the left hilum about the second interspace and to pass down anteriorly and to often curve in, and the linear marking comes nearer the anterior chest wall to the left of the heart.

It is not necessary for me to do more than to refer to the value of observing the movement of

the diaphragm upon the fluoroscopic screen, and to note whether or not it is adherent to the thoracic wall or drawn up by adhesions. Certainly you all know that diaphragmatic hernia can easily and accurately be diagnosed. But I do wish to emphasize that the posterior mediastinal space should be considered. It is simple to make this examination by oblique illumination upon the screen and a bolus of bismuth is so easily followed into the stomach that this observation should not be neglected.

But this is neither an x-ray paper nor a pathological study. It is an effort to call your attention to the fact that good x-ray chest plates are full of trunks and linear markings which can be studied stereoscopically; that each of these trunks contain bronchi and that when you can follow their distribution you can accurately locate your lobe or lesion before operation.

2503 Auburn Avenue.

AUTOSERUM-THERAPY (INTRASPINAL) IN ENCEPHALITIS LETHARGICA.

By I. C. BRILL, M.D.,

PORTLAND, ORE.

ASSISTANT PROFESSOR OF MEDICINE, UNIVERSITY OF OREGON MEDICAL SCHOOL.

There is at the present time a very active epidemic of lethargic encephalitis in the Pacific Northwest. During the past three months I have personally seen ten cases—all in Portland.

House[1] has recently reported thirteen cases. In the United States, the epidemic has existed since 1918. Numerous reports have been published in the past two years. Perhaps the most exhaustive clinical study of the disease was made by Barker[2] and his collaborators, report of which has just appeared while this paper was being prepared. Vaughan[3] has recently presented a complete review of the earlier literature on this subject. And though the clinical features of this disease are now clearly understood, no suggestion as to therapy has yet been offered. Economo[4] in his monograph on Encephalitis Lethargica states that: "No known measures of therapy have influenced the course of the disease."

For several years I have been actively interested in *intraspinal autoserum-therapy* in various nervous disorders, both acute and chronic. And when the problem of the present epidemic presented itself it occurred to me that the use of autogenous serum intraspinally might be of some value. I recalled the effects of this mode of treatment in acute chorea (probably also an infectious encephalomyelitis). Since I have never seen any ill effects from the operation and since no other therapy has as yet been offered, I felt justified in proceeding with this mode of treatment. I have treated five cases by this method. In four of these the improvement was definite, rapid, and marked. In the fifth case, the patient was in moribund condition with signs of rapidly developing pneumonia, when a single injection of autogenous serum was given intraspinally. The following day the patient's condition appeared to improve, but on the third day he died of pneumonia.

The technique is simple. It consists briefly of obtaining from the patients from 60 to 100 c.c. of blood. The blood may be received in a flask and allowed to stand over night and the serum separated the following morning. Or the blood may be received directly into centrifuge tubes and the serum separated for use the same day. A lumbar puncture is performed in the usual manner and 25 to 35 c.c. of spinal fluid is withdrawn and an equal amount of the patient's blood serum is injected into the subdural space. The foot of the bed is raised 6 to 8 in. for three to four hours. Strict asepsis must be observed in the preparation of the serum and in the operation.

In the beginning of my work I used to inactivate the serum in a water bath at 56° C. for thirty minutes. I have found, however, that this practice is unnecessary and probably even undesirable, since it no doubt destroys some antibodies during the process of inactivation.

Case I.—Male, age 27, salesman. Referred for diagnosis November 29, 1919. Complains of nervousness, and difficulty in walking. Family history unimportant, personal history: Grippe in 1912; no other illness. Denies venereal disease. Married one year, one healthy child, six weeks old. Present illness began seven weeks ago with a sharp pain in the back, a little fever, which lasted for about three or four days, then he became drowsy and sleepy, noticed that he would see double. Speech became thick and right side of face became paralyzed. Within two weeks, the eyes began to improve and pain in back left. There was no headache or vomiting. Lost thirteen pounds in seven weeks. After the first two weeks he began to improve, but is still nervous, shaky, and very stiff, making walking extremely difficult.

Examination.—Mask-like expression of face, typical Parkinsonian gait. Pupils reacting very sluggishly to light and accommodation, knee-jerks hyperactive, the left slightly more active than the right, no clonus or Babinsky. Spinal fluid was under considerable pressure; 7 cells to the cubic millimeter; globulin, positive; gold. sol. test $\pm + + \frac{+}{+} + 0\ 0\ 0\ 0\ 0$. Wassermann negative. Blood Wassermann negative.

A diagnosis of lethargic encephalitis was made. The patient was observed for a period of four weeks, during which time his condition became distinctly worse. When seen a second time, December 22, he showed a much more marked spasticity in his gait, of the Parkinsonian type. His knee-jerks were much more exaggerated, the left being distinctly greater than the right, marked clonus on the left, Babinsky positive on the left side. Twenty c.c. of autogenous serum was introduced intraspinally after a similar amount of fluid was withdrawn. The next day, after a mild reaction, the patient was much improved. Spasticity was nearly entirely gone, there was no longer clonus or Babinsky on the left side, and the difference in the knee-jerks was less marked. A week later a second injection was given, and in three days the patient was able to come down unaided to be presented before the Portland City and County Medical Society. He was practically completely recovered, aside from a little weakness.

Case II.—Female, age 21, housewife. Referred by an eye specialist for diagnosis on January 15, 1920. She complains of blurred vision and headache; family history is negative; personal history presents nothing of importance. Married ten months, no conception. Her present illness began between two and three weeks ago when she began to grow tired and sleepy. Ten days ago she noticed that her vision became blurred and she was unable to real. Did not see double. The headache was much worse the last two weeks. Has not been able to sleep the last four nights, but feels sluggish and drowsy mentally. Jaws have been quite stiff for several days, making it very difficult to take food.

Examination.—Pupils unequal; right larger than the left; no reaction to either light or accommodation;

jaws are stiff; can't open mouth beyond one c.m. Heart and lungs negative, knee-jerks hyperactive, but equal. Mentality sluggish, answers questions very slowly. There is a double facial paralysis, the right being more affected than the left. Spinal fluid examination: 36 cells per cu. mm.; Globulin, positive; Wassermann, negative; Blood Wassermann, negative.

On January 26, 30 c.c. of autogenous serum were given intraspinally, and a second injection a week later. Improvement was marked, though less rapid than in Case I. She left the hospital February 18, feeling perfectly well, with the facial paralysis completely gone and vision fully recovered though the pupils still react very sluggishly to light and accommodation.

CASE III.—Male, age 42. Referred for diagnosis January 19. Chief complaint sleepiness and headache. Family history unimportant; personal history, never been ill, denies venereal disease. His present illness began two months ago with weakness and sleepiness, nausea and vomiting. Vision was blurred, but no diplopia present.

Examination.—Marked pallor. Has stuporous expression, due apparently to a bilateral ptosis of the upper eyelids. Weakness of both facial nerves; knee-jerks active and equal; mentality sluggish, answers questions slowly, pupils do not react to light or accommodation. Spinal fluid under much pressure: 100 cells per c. mm.; Globulin, positive, Wassermann, negative; Gold sol. test, $\pm + + \overset{+}{+} + \pm$ 0 0 0 0. Blood Wassermann, negative.

A single injection of 35 c.c. autogenous serum was given February 11, 1920. Improvement was very marked and rapid. Patient left hospital two days later, feeling well enough to return to work. On February 19 he was seen again in the office. His ptosis was still fairly well marked, but pupils reacted to light and accommodation, though rather sluggishly. Facial paralysis entirely gone and mentality is perfectly clear and he insists upon returning to work.

CASE IV.—(By courtesy of Dr. C. G. Sabin.)—Male, age 37. First seen January 10. Complains of stiffness of jaws and headache. Never been seriously ill, excepting for appendicitis two years ago, for which he was operated upon. Denies venereal disease. Present illness began two days ago, with dizziness. Did not think it was necessary to consult a physician, but soon became delirious and after two days became drowsy. Came to hospital on the fourth day.

Examination.—Pupils fixed, bilateral ptosis of upper eyelids; right facial paralysis, both jaws stiff; distance between upper and lower teeth one cm. January 22, diplopia noted for the first time. Ptosis of the left eyelid more marked than that of the right. January 23, patient very drowsy, slept most of the day. January 25, 20 c.c. serum given intraspinally. Spinal fluid examination: 100 cells per c. mm.; Globulin, positive; Wassermann, negative.

January 28, general condition much better. January 29, patient up and about, very good day. January 30, a second injection of 20 c.c. given intraspinally. Improvement continued.

Conclusion: Intraspinal autoserum therapy appears favorably to influence the course of encephalitis lethargica, causing a rapid disappearance of motor disturbances and mental depression. Although the cases observed were few, the improvement was so marked and following so rapidly upon the use of autogenous serum that it appears justifiable to draw such conclusions.

In closing, I wish to express my thanks to Dr. C. G. Sabin for furnishing the data in Case IV, and for permitting me to follow with him the course of the case.

JOURNAL BUILDING.

THE PREVENTION OF PERITONITIS IN A CASE OF INTRAPARTUM INFECTION SUBJECTED TO EXTRAPERITONEAL CESAREAN SECTION.

BY R. A. BARTHOLOMEW, A.B., M.D.,

ATLANTA, GA.

ASSOCIATE IN GYNECOLOGY AND OBSTETRICS, EMORY UNIVERSITY SCHOOL OF MEDICINE.

THE following case has seemed to the writer worthy of reporting on account of the fact that this particular method of performing cesarean section was subjected to a most rigid test and was successful in the object sought, that of preventing peritonitis in a case undoubtedly very badly infected.

W. B. C., colored (Grady Hospital No. 1,378), aged 18, was admitted to the hospital at 7 A. M., December 6, 1919, at full term in her first labor. Her last period occurred March 1, 1919, and there had been no complications during the pregnancy. On the day preceding admission to the hospital the membranes ruptured prematurely at 4:30 A. M., while the patient was asleep, and labor pains began about five hours later. She was attended by two midwives, who made frequent vaginal examinations and tried to dilate the cervix manually. Failing in this and noting no progress, they sent the patient into the hospital the following morning.

On admission the temperature, pulse, and respiration were normal. She appeared to be of normal development and the heart, lungs, and blood pressure were normal. The fundus reached to the ensiform, and the child, apparently a rather large one, was in the R. O. A. position, the head being markedly flexed but not well engaged. The heart sounds were normal. The measurements were as follows: Interspinous 21 cm.; intercristal 23 cm.; external conjugate 18.25 cm.; external obliques 19.75 cm.; bitrochanteric 29.5 cm.; bisischial 9 cm. Contractions were occurring at three to four-minute intervals and there was a continual slight watery discharge. Rectal examination showed the cervix to be half dilated and an absence of a sac of waters.

On account of the previous exposure to infection the patient was allowed to continue the test of labor in the hope that the head would mold sufficiently to pass through the generally contracted pelvis or at least progress far enough to be delivered with forceps. The pains continued throughout the day with good frequency, duration, and severity and the fetal heart sounds continued normal, but there was no advance of the head.

At 4 P. M. the temperature, pulse, and respiration were found to be 100°, 118, 24; at 9.30 P. M., 101°, 120, 24, and at 11.30 P. M., 102°, 130, 26. With this evidence of intrapartum infection and being unable to find any other cause for the increase in temperature, pulse, and respiration, it was decided to attempt delivery with forceps and failing in this, to sacrifice the child, if necessary, by craniotomy, as the infection was considered to be too severe to avoid peritonitis by any form of cesarean section, extraperitoneal or otherwise.

Under ether, the dilatation of the cervix was completed manually and the head was found to be movable at the inlet and the membranes ruptured. Forceps was applied with great difficulty, but several test tractions accomplished nothing. Pubiotomy was considered almost, if not as much contraindicated as any form of cesarean section on account of infection. Hence,

although the fetal heart was still good, it was decided to do craniotomy and sacrifice the child, the pelvis being considered sufficiently large for this method of delivery.

The head was perforated with some difficulty, owing to its movability, and the Simpson cranioclast applied, crushing the head anteriorly and posteriorly in successive portions, expelling the brain substance and reducing the size of the head until the entire vault was destroyed down to the base. But even then it was found to be impossible to draw it through the inlet. By this time the patient was in a condition of marked shock with a pulse of 170 to 180, and efforts to deliver her were temporarily stopped to stimulate her hypodermically and with intravenous saline and adrenalin. Her pulse improved at once and cesarean section was decided on as a last resort.

A low abdominal incision was made and before entering the uterus the edges of the opening in the parietal peritoneum were sutured by a continuous locked stitch, to the uterus, outlining an area sufficiently large to permit delivery of the child according to the method described in DeLee's Text Book on Obstetrics and also by Cherry in the *American Journal of Obstetrics*, October, 1917. The uterus was then opened and an eight-pound female child easily extracted without injury to the peritoneum surrounding the incision. The placenta and membranes were removed and pituitrin was injected into the uterine muscle and iodoform gauze packed into the cavity to lessen bleeding. The incision in the uterus was then closed with interrupted and continuous catgut sutures. The parietal peritoneum fastened to the uterus was not disturbed. The muscle, fascia, and skin were closed except for an opening through which a piece of rubber tissue was left in place to drain down to the uterus.

The patient was then given further stimulation with pituitrin and ergotole hypodermically and saline under the breasts, and she reacted well. Five hours after operation her temperature, pulse, and respiration were 105°, 168, 36. Sodium carbonate and glucose retention enemas were given and the patient was kept well under the effect of morphine. There was marked distention for several days, but no nausea, constipation, abdominal pain, or tenderness to indicate peritonitis. The distention subsided and the patient gradually improved, the pulse coming down to 100, although the wound suppurated and broke down almost completely, with free purulent drainage and lochia.

On the twenty-first day after operation, the left leg became markedly swollen and the pulse and temperature increased. Vaginal examination showed evidence of cellulitis in the left parametrium. Delirium gradually developed and the condition steadily became worse, death occurring January 6, one month after operation.

At autopsy the principal findings were as follows: A number of small vegetation and ulcers were found on the mitral valve and there were several small infarcts in the lungs. The abdomen showed no evidence of peritonitis, there being no adhesions whatever in the pelvis surrounding the uterus; the uterus itself was quite firmly adherent to the abdominal incision and fairly well involuted, the cavity of the uterus communicating with the outside through a small suppurative tract. The veins in the left broad ligament were firmly thrombosed and this thrombosis could be followed into the left ovarian vein almost up to the renal vein; the left femoral, external iliac, and common iliac veins were almost occluded with partially organized thrombi extending into the inferior vena cava where the thrombus was broken down and liberating pus into the circulation. There was some retrograde thrombosis into the right common iliac vein. After removing the pelvic organs, the true conjugate of the pelvic inlet was found to measure 8 cm. and the transverse 10 cm., indicating a relatively greater contraction in the transverse than in the anteroposterior.

The significant feature of the case is the fact that, notwithstanding the severe degree of infection which must have been present, this particular method of performing the section was successful in preventing general peritonitis, which is the usual cause of death after cesarean section performed on infected cases. Thrombophlebitis is a relatively infrequent complication and had the patient not been so unfortunate as to develop this complication she would most probably have recovered.

This technique is much simpler and quicker than the true extraperitoneal method described by Latzko, whereby the lower segment of the uterus is reached through the space of Retzius by pushing the bladder aside and the peritoneal fold upward, but it has the possible disadvantage of leaving an abnormal peritoneal attachment of the lower segment of the uterus to the anterior abdominal wall. If, in such a case, a persistent fistula remained, it would seem quite possible to remove the scar of the abnominal incision, together with that of the uterus, repairing both and restoring the parts to their normal relation.

In conclusion, my only excuse for reporting an isolated case of extraperitoneal cesarian section is the fact that this method of operating, which, although simpler, is not supposed to be as certain in its protection against peritonitis as the true extraperitoneal method, was, nevertheless, successful in preventing peritonitis in a case undoubtedly severely infected and any method which will tend to do away with craniotomy on the living viable child, is indeed worthy of continued trial until its value can be finally settled.

746 Peachtree Street.

Medicolegal Notes.

Death by Disease, Accelerated by Accident, Does Not Warrant Recovery on Accident Policy.—In an accident against an insurance company for death under an accident policy, the utmost that could be found in favor of the plaintiff from the evidence was that the deceased, at the time of and prior to a fall which he sustained while returning to his chamber from the cellar of his home, was suffering from a seriously diseased condition of the heart or lungs, or both, which was precipitated to a fatal termination by the fall, but which probably would not have terminated thus on that day but for the fall. Such fall would not have been fatal except for the diseased condition of vital organs. These two causes, namely, the diseased condition and the fall, operated together, each contributing to the fatal result. It was held that, if the insured was suffering from a disease which was accelerated and aggravated by the accident so as to be a cause cooperating with it to produce the fatal end, then there could be no recovery. Manifestly, however, recovery is not barred merely because the insured is suffering from disease. One upon a bed of illness may meet death by an explosion or other accidental means. If there is no active disease, but merely a frail general condition, so that powers of resistance are easily overcome, or merely a tendency to disease which is started up and made operative, whereby death results, then there may be recovery even though the accident would not have caused that effect upon a healthy person in a normal state.

The inevitable result was that the plaintiff could not recover upon the facts of the case. The deceased confessedly was suffering from disease or diseases which actively co-operated with the fall in causing death. The disease and the fall were concurring, efficient and proximate causes in producing the death. Either alone without the other would not then have resulted fatally. It could not be held with any due regard to the meaning of words in the contract here sued upon that the death of the insured resulted from the accident "alone and independent of all other causes," as "the proximate, sole and only cause."—Leland v. Order of United Commercial Travelers, Massachusetts Supreme Court, 124 N. E. 517.

CHRONIC APPENDICITIS.

A SCANNING of the operation lists of any large general hospital will reveal the presence of a large number of appendectomies performed for chronic appendicitis. The pathologist is apt to be sceptical of the correctness of this diagnosis in many instances for he is unable to find much more change in these appendices than he frequently finds in such organs removed at autopsy or for prophylactic purposes during the course of abdominal operations. The medical man is only too prone to smile at a diagnosis which he thinks may be made in the lack of something better. The obvious method for the correction of this situation is to make a careful study of the results of these operations and to determine, if possible, the causes of the failures. This has recently been done by Gibson (*Am. Jour. Med. Sci.*, 1920, clix, 654) who has reviewed the results of 555 operations performed during the past six and one-half years. In 102 of these cases (18.3 per cent.) the result was classed as unsatisfactory although in the majority of them a definitely pathological appendix had been removed, because the patient continued to complain of various symptoms, chiefly abdominal pain.

After a careful analysis of these cases, Gibson concludes that the chief causes of these unsatisfactory results are the formation of adhesions after operation and a failure to explore the peritoneal cavity thoroughly at the time of the operation. He notes a distinct improvement in his figures during the last six months of the period of his study and suggests that it may be due to the fact that he has substituted picric acid for iodine as a solution used in preparing the skin for operation. It has been suggested that iodine from the skin carried into the peritoneum on the surgeon's gloves may be a principal factor in the causation of adhesions because of its great irritating properties. In regard to the importance of exploration he discusses the fact that the diagnosis of chronic appendicitis is often very difficult to substantiate without operation and points out that it is not infrequently associated with lesions in the upper abdomen. He warns the surgeon not to be content when he finds a definitely pathological appendix but in any case to look further to see whether there be any other lesions that later may keep up the patient's symptoms. In addition he insists upon the importance of a careful and detailed history, a matter which cannot be emphasized too strongly. Unfortunately the student and the interne, those who take the histories in the hospital, rarely appreciate the importance of this, and the task of history-taking is considered to be much of a bore. Of course any experienced physician will immediately admit the importance of an accurate and detailed history but it has been difficult to impress this upon the beginners. Gibson also recommends the use of a "good-sized incision" through which it will be possible to inspect other parts of the abdomen.

This critical study should yield excellent results if others will take the author's admonitions to heart. He is frank to admit his own difficulties and proposes remedies which should have a broad and early trial in order to determine their value. Early report of the results of others will contribute to clear up a situation that is annoying to all surgeons and to a certain extent an injustice to these patients.

THE POSTOPERATIVE COMPLICATIONS FOLLOWING EXCISION OF VARICOSE VEINS.

THE postoperative complications which may occur after excision of varicose veins arise either immediately after the operation or during convalescence. Immediately after the operation hematoma, local suppurative processes, sloughing of the skin incisions, and temporary loss of sensibility in the cutaneous areas surrounding the incisions have all been recorded. Therefore, great attention should be given to hemostasis, because of the very large number of veins divided during the interference, as well as their size. The perforating veins are to be particularly attended to as their ligation is often a delicate matter on account of their brevity, as well as their intra- and subaponeurotic situation. Often they do not bleed at all, or very little, at the time they are divided, on account of the position and inertia of the limb during the operation, and begin to bleed only when the patient commences to move the member. A moderately compressive dressing should be applied, the compression extending especially over the calf of the leg, as this is the most extensive subcutaneous raw area. When a hematoma occurs it will have no other effect than to delay union, but it should be opened and drained in order to hasten cicatrization. It is most essential to wait until the ulcer or ulcers have become cicatrized before attempting excision of the varicose veins, otherwise asepsis will be imperfect and the result will be suppuration of the wound; and the removal of the underlying veins cannot be accomplished unless the ulcer has healed. If cicatrization of the ulcer has not taken place the operation should be done in two successive stages, the first being excision of the veins far removed from the ulcer with suture of the incision, and secondly excision of the veins surrounding the ulcer. When

suppuration does occur it is usually mild and will not compromise the operative result.

Necrosis of the borders of the incisions is not uncommon. It is not the result of extensive operative detachment of the integument, for when the skin is of good quality and aseptic it can be detached to the extent of eight or ten centimeters on each side without giving rise to necrosis. Necrosis may occur in those areas of skin which have been the site of eczematous or ulcerative lesions, for the territory on which an ulcer has previously existed remains septic for quite a long time after repair has taken place. In these circumstances the sloughing will occur in small areas measuring a few millimeters in diameter, although, occasionally, they may be more extensive; but speaking in a general way, the necrotic process will not interfere with a good ultimate operative result. To avoid the occurrence of sloughing supplementary incisions should be made when the quality of the skin is doubtful.

A loss of sensibility has been noted sometimes in the cutaneous flaps, but this phenomenon is only temporary, and usually the sensibility progressively returns, becoming normal in a few weeks. It is evident that pains should be taken to avoid division of the nerve fibers during operation as far as possible.

During convalescence, when walking is begun, pain in the ankle and instep may be complained of; likewise stiffness of the limb and edema of the leg are usually present. These phenomena are the result of temporary disturbance of the return circulation and immobilization; daily massage and hot douching will hasten their retrogression. Edema of the limb is particularly prone to occur on standing, in subjects who have had a deep-seated phlebitis—posttyphoidal, for example—before the varicose veins developed, and in these circumstances it is apt to persist for some time. In some cases cheloid has been observed at that part of the incision passing over the internal condyle of the femur, and is due to friction from the clothes; therefore the complication can be avoided by ordering a bandage to be worn over this region.

MEDICAL LITERATURE.

THERE are several "legitimate" ways by which a doctor can make his existence known. One of these is by contributing to "the literature." One who has occasion to look up the literature on any subject will sooner or later—usually sooner—encounter articles which tend more to get the writers into print than to get the problems at issue any nearer to solution. One writer, as have many before him, comes out vigorously in favor of a ductless gland or two as explaining this or that symptom, quoting many a foreign and domestic observer to support his contention. Concerning the same symptom, another writer holds forth as stoutly, citing as many observers for focal infection. There are many debatable points which may serve to bring one out of the darkness into the light.

Some laboratory man finds an organism where no one else has found it, or catches an old organism doing something which has escaped other observers foreign and domestic, and behold, those who would keep up with the literature find themselves reading about it forthwith. Thus editors are constantly confronted with their ancient task of distinguishing gems from paste, real contributions from legitimate advertisements. And how much do editors positively know about the endocrinopathies, the viruses, the germs, which call forth so many observations? The profession is doing a great deal of work which is bound to vary in value. Editors are naturally loath to reject articles which might later prove to be of immense value. "Scooping" is by no means peculiar to the lay press. Moreover, original work should be encouraged and brought to general notice.

No matter how careful editorial boards may be, it looks as though readers of medical journals must expect to find occasionally something that is of value to the writer rather than to the reader, and must do their own selecting as they go along. They should bear in mind, too, that many really great scientists have made carefully considered observations which have not stood the tests of time and further research, while others with less science but more acute reasoning faculties have offered contributions, seemingly trivial, which eventually proved to be the foundation of a discovery of great value. These two tests of time and experience are far superior to any which an editorial board can apply. Meantime let the readers remember that it is through the medical journals that the profession keeps track of current medical effort; that however well the editors may do, the profession itself must eventually decide whether or not the article is a real contribution to science.

LAENNEC AS A POET.

THAT Laennec was a many-sided man becomes more and more apparent as the French medical journals continue to publish hitherto unsuspected facts concerning the great man's accomplishments and preferences. In the *Bulletin Médical* for May 22, 1920, xxxiv, 27, a contributor gives a poem, written when the author was 22, on the subject of love. Laennec read fluently almost everything that was worth reading, for he knew Latin, Greek, Italian, and English, in addition, of course, to French and Celtic—his native Bas-Breton. It is highly probable that he read German. While there is no mention of the Iberian languages these should also have been easy for him. His career as a poet began at the age of 17, when he wrote in Bas-Breton in verse a "letter to farmers." The MS. of the poem on love is extant and written in a beautiful, fine hand which recalls that of Poe. It almost appears as if the poet felt that he was writing for posterity, for the fine quality of the paper, stamped, and with gilt border, and the calligraphic writing cause the document to look fresh even after 122 years. The poem on love was ad-

dressed to two cousins. The lady, "Nisa," who really inspired the poem, is believed to have lived in Nantes when Laennec was pursuing his medical studies, and it is supposed that he expected to wed her. The two families are known to have approved of the match, but the fate of the young woman, as well as her identity, remains unknown. It is known that Laennec developed a profound streak of melancholy about this time, which is not explained by his poor health, for he would have been more likely to have shown the characteristic optimism of the consumptive.

PSYCHOTHERAPY AND MORPHINE ADDICTION.

CAMINO reports the case of a young woman, married and markedly hysterical, who became secretly addicted to morphine (*La Medicina Ibera*, 1920, xi, 129). For 4 years she had injected the drug daily, the amount having reached 2½ grams in 24 hours. Denutrition was intense and the patient suffered from nocturnal hallucinations of terrifying character. The picture was an extreme one, yet the author succeeded in effecting a cure in the patient's own home. He first told the woman that he would wean her gradually from the habit, incidentally substituting for muriate of morphine an amount of opium extract equal to the decrement in the former. The fraction of decrease was to be three centigrams daily. The only attendant was the husband. All went well until the daily dose was reduced to one gram. Here the patient's will succumbed and the author began to resort to hypnosis. The notably hysterical make-up of the patient made the outlook somewhat favorable. Considerable time was required to produce full hypnosis and there were numerous preliminary sessions. Once the state was induced, the patient responded without fail to post-hypnotic suggestion. The author sought to produce a horror of and repugnance to the drug, at the same time injecting plain water, which he told her was the drug and which would produce nausea and other disagreeable symptoms. These she actually developed, and when given a syringe and morphine to use at pleasure actually threw them away. The period of cure required four months. The author is not entirely clear as to the method by which the irreducible minimum of morphine was suppressed, but apparently this was effected through the aid of suggestion and was fully accomplished before the experiment of inspiring disgust for the drug was made.

News of the Week.

Bubonic Plague in Mexico.—The first fatal case of bubonic plague has been reported at Tampico, the oil center of the east coast of Mexico. The American Consul at Tampico has been appealed to for aid, including the immediate dispatch of vaccines and serum. Out of the twenty-four cases of bubonic plague at Vera Cruz twenty-three have been fatal. The Consul at Vera Cruz has acknowledged receipt of vaccine and other medical supplies from the United States. The Mexican authorities have destroyed railroad tracks for five miles on all lines leading out of the city of Vera Cruz, in order to stop traffic with the interior, and thus prevent the spread of the plague. A death from bubonic plague was reported in Galveston, Texas, on June 17.

Salute the "Greatest Mother."—The army reorganization bill recently passed by both branches of Congress confers "assimilated rank" on members of the Army Nurse Corps. The superintendent is to have the rank of Major, the Assistant Superintendent, Director and Assistant Directors the rank of Captain; the chief nurses the rank of First Lieutenant, and other nurses are to be Second Lieutenants. "Assimilated rank" carries with it limited authority, but not the power of command incident to a line of officers of similar grade. The only incidents of absolute rank, according to the interpretation of the *American Legion Weekly*, are: The dignity incident to the name of the rank; the right to wear the insignia thereof; the eligibility to exercise authority within the limits set forth in the law, which are as follows: As regards medical and sanitary matters and all work in the line of their duties, they shall have and be regarded as having authority in and about military hospitals next after the medical officers of the army.

Tuberculosis Research Fellowship.—To encourage study of the means for the prevention and cure of tuberculosis, the Hennepin County Tuberculosis Association of Minneapolis, Minn., announces that it has set aside a fund for the support of a tuberculosis research fellowship in the Graduate School of the University of Minnesota. The candidate for the fellowship must be a graduate of a Class A medical college. He will be expected to devote himself to research in some problem concerned with the causes, prevention, or cure of tuberculosis. No teaching or other service will be required. The fellowship yields $750 the first year and progressively increasing amounts to be appropriated for the second and third years as conditions warrant. Inquiries and requests for application blanks should be addressed to the Dean of the Graduate College, University of Minnesota, Minneapolis, Minn.

Another Vivisection Investigation.—The Allied Medical Association, of which Dr. Ignaz Mayer is president, will appoint a committee of three to investigate cruelty in connection with vivisection, the committee to report to the association at the meeting next year.

Decrease in Infant Mortality.—Statistics compiled by the census bureau on infant mortality record that the death rate of infants under one year of age in New York city has decreased 11 per cent. as compared with 1918 and 18 per cent. as compared with 1915. The greatest decrease for the entire country is found in Lackawanna, N. Y., which records an improvement of seventy-four for every thousand births. Seven of the largest cities show decreases of from 8.5 to 23.4 per cent., with the highest increase at only 3.6. Percentage decreases over the year 1918 are recorded in other cities as follows: Philadelphia, 33; Cleveland, 3; Baltimore, 51; Detroit, 4; Pittsburgh, 25; Buffalo, 11; Milwaukee, 5; Washington, 37; Cincinnati, 16; Minneapolis, 8.

"Walking Doctors" Becoming Extinct Species?—According to a recent investigation by the

National Chamber of Commerce, it has been estimated that two-thirds of the doctors of the United States own automobiles. More than ninety per cent of country doctors are said to own passenger cars.

New Professional Building Proposed.—A building for physicians and dentists is being planned for the Yorkville section of New York City, according to real estate news.

General Gorgas Seriously Ill.—According to advices from London under date of June 17, Major General William C. Gorgas is seriously ill in a London hospital. The stroke of paralysis from which he was thought to have rallied has proved more serious than at first was thought. His mission to the West Coast of Africa for the purposes of investigating sanitary conditions for the Rockefeller Foundation has been abandoned, and General Gorgas will probably return to this country as soon as his condition permits. Other members of the party, headed by Brigadier-General Robert E. Noble, Medical Department, U. S. Army, will proceed on the tour of investigation.

Fiske Prize Awarded.—Dr. ALLEN G. RICE of Springfield, Mass., has been awarded the two-hundred dollar prize offered under the provisions of the will of the late Dr. Caleb Fiske of Providence, R. I., for the best essay on a given subject relating to medicine and surgery. The subject for this year was "Surgical lessons of the great war." Dr. Rice won the same prize in 1912 and again in 1916.

Dr. Gustav Zander, the Swedish physician who originated the Zander system of medico-mechanic gymnastics, died June 17 at Stockholm, at the age of eighty-five.

Dr. S. Griffith Davis, of the Research Committee of the National Anæsthesia Research Society, has been made professor of anesthesia in the University of Maryland. Several years ago this institution created a separate department of anesthesia, placing Dr. Davis in charge with the title of associate professor. So far as records are available, this is the first professorship of anesthesia to be created in the United States.

War Losses of France.—Captain Andre Tardieu, former French High Commissioner in the United States, has issued a comprehensive statement of the losses sustained by France during the world war. According to this report 8,000,000 men were mobilized by France during the five years of the war, 1,400,000 of whom were killed, 800,000 maimed, and 300,000 wounded. The country thus lost 57 per cent. of her men under thirty-two years of age. It is further stated that 600,000 houses were destroyed, 75,000,000 acres of arable land laid waste, and 3000 miles of railroad and 25,000 miles of highways destroyed. Mines which produced 55 per cent. of France's total coal output were damaged or destroyed; 11,500 factories, which before the war produced 95 per cent. of the woollen goods, 90 per cent. of the linen material, 70 per cent. of the sugar and 60 per cent. of the cotton goods, were crippled. One-third of France's ships were sunk by German submarines. To defray the cost of munitions of war and food supplies, France had to raise more than 8,000,000,000 frances, of which sum she was forced to lend 1,320,000,000 to foreign countries.

Medical Society Elections.—THE WESTERN ELECTRO-THERAPEUTIC ASSOCIATION, at its annual meeting in Kansas City, May 27-28, elected the following officers for the ensuing year: *President*, Dr. B. B. Grover, Colorado Springs (re-elected); *First Vice-President*, Dr. S. Grover Burnett, Kansas City; *Second Vice-President*, Dr. H. W. Nye, Osborne, Kansas; *Treasurer*, Dr. Charles Keown, Independence, Mo. (re-elected); *Secretary*, Dr. Charles Wood Fassett, Kansas City; *Registrar*, Dr. E. A. Nelson, Phillipsburg, Kansas (re-elected); *Trustees* (two years), Dr. W. P. Paterson, Springfield, Mo., and Dr. O. U. Need, Oak Hill, Kansas (re-elected). The next meeting will be held in Kansas City in May, 1921.

The CITY MEDICAL SOCIETY of Hartford, Conn., at its meeting on June 3, elected the following officers to serve for the coming year: *President*, Dr. William E. Hendry; *Vice-President*, Dr. Michael D. Riordan; *Secretary-Treasurer*, Dr. Clarence E. Simmonds.

THE AMERICAN PEDIATRIC SOCIETY, at its thirty-second annual meeting held in Highland Park, Ill., May 31 and June 1 and 2, 1920, elected the following officers for the ensuing year: *President*, Dr. John Howland, Baltimore; *Vice-President*, Dr. Charles Fife, Philadelphia, Pa.; *Secretary*, Dr. Howard Childs Carpenter, Philadelphia; *Treasurer*, Dr. Charles Hunter Dunn, Boston; *Recorder and Editor*, Dr. Oscar M. Schloss, New York.

Obituary Notes.—Dr. A. L. R. Avant, city physician, Savannah, Ga., died June 7, at the age of sixty-three. He was graduated from the Atlanta Medical College in 1893, and specialized in gynecology.

Dr. JOHN WARREN LITTLE of Minneapolis, Minn., died in Hill Crest Hospital in that city June 5, at the age of sixty-one. He was graduated from Jefferson Medical College in 1883, specializing in surgery. He was one of the founders of and was surgeon in the institution in which he died. Dr. Little was also professor of clinical surgery at the University of Minnesota for twelve years, chief of staff at Asbury Hospital, surgeon to the Minneapolis General Hospital, and official surgeon to the Chicago Great Western Railroad. He was a former president of the Minnesota Academy of Medicine; the Hennepin County Medical Society; the Minnesota State Medical Association; was a member of the American Medical Association and was a fellow in the American College of Surgeons, of which organization Dr. Little was a charter member.

Dr. CHARLES JORDAN, one of the oldest physicians in the state, died June 6, at his home in Wakefield, Mass. He was born in Saco, Me., in 1828, was graduated from Dartmouth Medical School in 1859, and entered practice in Wakefield immediately after his graduation. He had been a member of the Middlesex East District Medical Society since 1859, outliving all members who were in the Society at that time.

Dr. JOHN THELBERG of New York City died June 7. He was graduated from New York University Medical College in 1887. He was a member of the American Medical Association and of local and state organizations.

Dr. WILLIAM H. FALLS of Cleveland, Ohio, formerly of Cincinnati, died June 7, at the age of seventy. He was graduated from Miami Medical

College, Cincinnati, in 1873. He was a member of the American Medical Association.

Dr. CHARLES SARAPHIN RODIER, who had practised medicine for twenty-seven years in Manchester, N. H., died June 8, at the age of fifty-five. Dr. Rodier was born in Montreal, Canada, and was graduated from Victoria College in that city.

Dr. HERBERT TETLOW of Stonington, Conn., and Westerly, R. I., a retired physician, was shot and killed in his home June 11. Mrs. Alfred Kenyon of Westerly admitted having committed the deed. Dr. Tetlow, who was fifty years of age, was graduated from Western Reserve University School of Medicine in 1899.

Correspondence.

WILLIAM T. G. MORTON, THE DISCOVERER AND REVEALER OF ANESTHESIA, AND HIS PLACE IN THE HALL OF FAME.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—On April 10 you were good enough to publish my open letter, entitled, "No Physician or Surgeon as Yet in the Hall of Fame." As you will recall, I deplored the fact that no physician or surgeon had as yet been found worthy to be named among the great American immortals. I ventured to suggest as the three most worthy names, William T. G. Morton, the discoverer of ether anesthesia; Ephraim McDowell, the first surgeon to perform a rational, deliberate, and successful ovariotomy, and J. Marion Sims, a great gynecologist, who perfected the plastic operation in the vagina for the relief of vesical fistulæ and invented the speculum. I stated that the nominations should be sent to the Senate of the New York University, University Heights, New York City, and that this should be done by every American physician who feels the great injustice done to the American medical profession by the apparent neglect or oversight of the previous electors.

I received many letters of approval of my humble efforts, and of my choice of the three names mentioned. A few of my correspondents, however, objected to the name of William T. G. Morton as not being the discoverer of surgical anesthesia, and in the *Journal of the American Medical Association* of April 24 there appeared a strong letter, signed by Dr. S. J. Lewis, according to which the priority of the discovery of sulphuric ether as an anesthetic belongs to Dr. Crawford W. Long. It would lead to no result to recall here all the details of the old controversy between Morton, Long, and Jackson of half a century ago; the fact remains that before any one of these three men thought of the subject of anesthesia, means to subdue pain by all sorts of physical agents, such as various vapors, lotions, etc., were employed, and even hypnosis was resorted to by Esdaile and Elliotson (1790-1868), who operated upon hundreds of patients in the hynotic state. Granted that Crawford W. Long discovered the anesthetic properties of sulphuric ether before Morton, he did not make known this method of producing sleep. Long did not prove to the medical profession that surgical anesthesia with the aid of sulphuric ether was "certain, safe and complete." These words were used by Dr. Henry J. Bigelow, a member of the staff which was present during the operation on that memorable day of October 16, 1846.

Concerning the priority claims of Long and Jackson, Dr. J. Collins Warren, Moseley Professor of Surgery, Emeritus, Harvard University, who wrote me only recently in reference to this matter, very pertinently says: "It is probable that Long performed three or four minor operations with primary anesthetic and then abandoned his claims. As Dr. Keen says, he is deserving of nothing but censure for not having appreciated the value of the agent." Regarding the claims of Jackson and his heirs, it may be briefly stated that the consensus of medical opinions in Boston at the time was and still is that his claim was not accepted.

The question resolves itself into what is meant by priority in the case of a great discovery. In Owen's "Homologies of the Skeleton" we read the following definition of priority: "He becomes the true discoverer who established the truth, and the sign of the truth is the general acceptance. Whoever, therefore, resumes the investigation of neglected or repudiated doctrine, elicits its true demonstration, and discovers and explains the nature of the errors which have led to its tacit or declared rejection, may certainly and confidently await the acknowledgments of his right in its discovery."

Francis Darwin, in *Eugenics Review*, 1914, makes it still clearer when he says: "In science the credit goes to the man who convinces the world, not the man to whom the idea first occurs." Morton convinced the world; the credit is his.

The late Sir William Osler, our greatest modern medical historian, to whom I referred in my first communication, considers Morton the inventor and revealer of anesthesia by sulphuric ether, and he speaks of him as a new "Prometheus who gave a gift to the world as rich as that of fire, the greatest single gift ever made to suffering humanity." He pertinently asks in one of his latest essays on the subject ("Annals of Medical History," Vol. I, No. 4):

> Why do we not give the credit to Dioscorides, who described both general and local anesthesia, or to Pliny, or Apuleius, or to Hiotho, the Chinaman, who seems to be next in order, or to the inventor of the spongia somifera, or to Master Mazzeo Montagna, in Boccaccio, or to any one of the score or more of men in the Middle Ages who are known to have operated on patients made insensible by drugs or vapors?

In addition to the testimony of Osler, that to Morton and to no one else should be given the credit, I may quote the following paragraph from a personal letter sent to Mr. E. L. Snell by Oliver Wendell Holmes on April 2, 1893 (*Century Illustrated Magazine*, August, 1894):

> Few persons have or had better reason than myself to assert the claim of Morton to the introduction of artificial anesthesia into surgical practice. . . . This priceless gift to humanity went forth from the operating theater of the Massachusetts General Hospital, and the man to whom the world owes it is Dr. William Thomas Green Morton.

A further evidence that to Morton should be given the credit, I will cite a paragraph from an address by Prof. William H. Welch of Baltimore,

delivered on October 16, 1908 (the 62nd anniversary of Ether Day), as follows:

The attendant circumstances were such as to make the operation performed on October 16, 1846, in the surgical amphitheater of this hospital, by John Collins Warren, upon the patient, Gilbert Abbott, placed in the sleep of ether anesthesia by William Morton, the decisive event from which date the first convincing public demonstration of surgical anesthesia, the continuous, orderly, historical development of the subject, and the promulgation to the world of the glad tidings of this conquest of pain. Had this demonstration or any subsequent one of like nature failed of success it is improbable that we should have heard much of claims to the prior discovery of surgical anesthesia.

I hope this will suffice to settle the controversy for good and that this letter may be as widely published in the medical press as was my first one on this subject.

Dr. Charles H. Mayo, one of the electors of this year, writes me as follows: "It is a sad commentary that no medical man's work has been considered of sufficient importance to warrant a tablet in the Hall of Fame." Let there be no longer a division as to the nomination of Morton for the Hall of Fame. All those who are willing to be helpful in this matter may write to the Senate of the New York University, or to any one of the 102 electors.

The final election will take place July 1. Fortunately we have this year among the electors no less than four medical representatives—Major General Leonard Wood, Prof. William H. Welch, and Drs. William J. and Charles H. Mayo. I hope the good and great general will forgive me for still claiming him as one of ours. A list of the 102 electors will be sent to any one addressing his request to the Secretary of the Senate of the New York University.

We should have not only William T. G. Morton, but also the two other great Americans already mentioned who belong to our profession in the Hall of Fame—Ephraim McDowell and J. Marion Sims. However, William T. G. Morton should be the first to be placed among America's great immortals.

It may not be universally known that Morton died virtually in poverty and heartbroken because he had received no recognition for his epoch-making discovery and daring experiment. I feel that I cannot close this ardent appeal for justice to "the inventor and revealer of anesthetic inhalation before whom in all time surgery was agony" better than by quoting one verse from "The Birth and Death of Pain," a poem by S. Weir Mitchell, M.D., read on October 16, 1896, at the Commemoration of the Fiftieth Anniversary of the First Public Demonstration of Surgical Anesthesia:

"How did we thank him? Ah! no joy-bells rang,
No paeans greeted, and no poets sang,
No cannon thundered, from the guarded strand,
This mighty victory to a grateful land!
We took the gift, so humbly, simply given,
And coldly selfish—left our debt to Heaven.
How shall we thank him? Hush! A gladder hour
Has struck for him, a wiser, juster power
Shall know full well how fitly to reward
The generous soul that found the world so hard."

S. ADOLPHUS KNOPF, M.D.

16 WEST NINETY-FIFTH STREET.

THE TWO CLASSES OF PHYSICIANS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In a letter by Dr. Beverley Robinson on "Some So-called Advances in the Practice of Medicine," in the MEDICAL RECORD of June 5, efficient hospital staff organization and attempts at accurate diagnosis are rather severely criticised, and we are advised that what the physician really does is to treat symptoms. The older men are characterized as busy men who advise and treat patients without laboratory aid, while the younger ones are supposed to harm their patients and poison their minds by means of misinterpreted laboratory reports of questionable value.

I had thought that physicians were classified differently—that some physicians, old and young, make sincere efforts to find the origin of their patients' trouble, using all means which they may have at their disposal so that, with the cause in mind, they may be able to relieve it. Others do not care to make accurate diagnoses, but by their presence at the bedside give patients a false sense of security, thereby depriving them of efficient medical aid and often deferring it until the patient's life is endangered or lost as a result of the delay. Such men may treat suppurative pleurisy as typhoid, pyonephrosis as malaria, and syphilitic arthritis as rheumatism. However, it would hardly seem just to put the older men "who have borne the burden and heat of the day" in this category. It could hardly be said that Sir William Osler contented himself with symptomatic treatment or that he did not try to make accurate diagnoses.

AUGUSTUS STREET, M.D.

VICKSBURG, MISS.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, May 28, 1920.

The Rising Birth Rate.—A rift in the cloud of gloomy prognostications, justified, to some extent, by the situation, is perceptible in the mounting birth rate of England and Wales. A striking rise in the English birth rate is recorded for the first quarter of the year. The number of births registered during the three months was 271,082, or 47,513 more than in the December quarter, and 126,162 above the total for the corresponding period of last year. As a matter of fact, it is the highest number recorded in any quarter since civil registration was established, and reaches the satisfactory annual rate of 29 per thousand of the population. It will be gathered from the table below, giving the rates for the calendar years 1910-1919, that the figure for the first quarter of the current year is greatly in advance of any attained during the past decennium. Rate per thousand for 1910, 25.1; for 1911, 24.3; for 1912, 23.9; for 1913, 24.1; for 1914, 23.8; for 1915, 21.9; for 1916, 20.9; for 1917, 17.8; for 1918, 17.7; for 1919, 18.5. The natural increase of population in England and Wales last quarter by excess of births over deaths was 133,445, against 14,810 and 24,303 in the first quarters of 1917 and 1918 respectively, and a natural decrease of 47,002 in the first quarter of 1919. Of the 271,082 births, 12,054, or 2,087 more than the number in the corresponding

quarter of 1919, were illegitimate. The births of males numbered 139,118 and those of females 131,964. Male births were in proportion to female births as 1,054 to 1,000, the average proportion in the ten preceding first quarters being 1,042. Deaths registered in January, February, and March numbered 137,637—22,877 more than in the December quarter, but 54,285 fewer than in the first three months of last year, when there was an exceptionally heavy mortality from influenza. It may be noted that only 4,037, or 2.9 per cent., of the deaths in the first three months of 1920 were attributable to this disease. Infant mortality, measured by the proportion of deaths under one year of age to registered births, was equal to 88 per thousand, being 32 per thousand below the average in the ten preceding first quarters, and the lowest recorded rate for any first quarter of the year. Statistics of the marriages which have taken place in this year are not yet available, but in the last three months of 1919 the number of persons who entered wedlock was 203,202, a figure equivalent to an annual rate of 21.5 per thousand of the population. This total shows a decrease of 9,192 on that for the September quarter, but is 53,094 higher than the number for the corresponding period of 1918. In the last ten years the rate of 21.5 was exceeded only in the June and September quarters of 1919 and the September and December quarters of 1915.

Nurses and Health Service.—According to the *Daily Telegraph*, May 20, 1920, the report which the Medical Consultative Council has presented to the Minister of Health is likely to be published at the end of May, and if its recommendations are translated into legislative action a great extension of the nursing service throughout Great Britain will be inevitable. The Consultative Council, it is understood, proposes to throw upon local authorities the obligation to provide a nurse for every patient who is certified by a doctor to require one. It is common knowledge that a large number of sufferers would not require indoor hospital treatment if they could obtain the assistance of nurses at home, but, owing to the impossibility of procuring skilled nurses, a medical man has no option but to recommend the transference of patients to hospital. It is claimed that, although this new obligation on local authorities would, at the outset, entail a considerable outlay of public money, it would, in the long run, effect a big economy in hospital accommodation, which is relatively far more expensive than accommodation at home. It is obvious that the adoption of the Council's recommendation would involve increase in the supply of skilled nurses.

New Medical Appointments by the Minister of Health.—The Minister of Health expressed his decision, some little time ago, to enlarge the scope of the Ministry so far as the medical side is concerned, and particularly as regards tuberculosis, general sanitation and epidemiology, venereal disease, international health work, and the administration generally with respect to infectious disease and the work of port sanitary authorities. In keeping with this decision, Dr. Addison has made several additional appointments to the medical staff of the Ministry.

The Association of Surgeons of Great Britain.—Sir John Bland-Sutton, who a few months ago was made president of the newly formed Association of Surgeons of Great Britain and Ireland, gave, during the week ended on May 15, last, a presidential address at the Royal College of Surgeons of England. Sir John is a good speaker and likewise a humorous one, and in his address he gave a clear exposition of why the new organization was established and the work that lay before it. In a previous letter it was explained that the prime mover in the project was Sir Berkeley Moynihan, who suggested its formation to the then president of the Royal College of Surgeons, Sir Rickman Godlee, in 1914. The war put an end for the time to the realization of the project, but since the armistice the matter was taken up again, with the result that the association is now an established fact. Sir John Bland-Sutton celebrated its inauguration by a dinner which he gave at Claridge's Hotel on the evening of May 13. At the dinner more than one hundred guests were present and some of the proceedings thereat are whimsically and graphically described in a special article contributed to the medical press of May 19. From this description it is plainly evident that the association has had a splendid "send off" and has begun under extremely favorable auspices.

National Health Insurance Bill: Removal from the Panel.—Capt. Elliott, the medical man who is now a member of Parliament and who has shown himself particularly energetic in the service of the medical profession, that is, so far as medical legislation is concerned, on May 11, ult., in the House of Commons moved that a new clause be inserted in the National Health Insurance Bill providing that: 1. Any medical practitioner aggrieved by a decision of the Minister, or of any special body through which the powers and duties of the Minister under the National Insurance Act are exercised, to remove his name from any list of medical practitioners may appeal against the decision of the High Court within the time and in the manner and on the conditions directed by the rules of the Court. The contention of Capt. Elliott was that by terms of the act the medical practitioner lost to a very large extent his independence, and was made subservient to the Minister of Health and the officials of the Ministry. In fact, that a bureaucracy had been established whereby the panel practitioner was no longer a free agent. Dr. Addison, the Minister of Health, said that the bill did not extend the power of the bureaucracy, but Capt. Elliott pointed out that the Minister was a new Ministry and here was a new bureaucracy. Dr. Addison went on to say that there was no word in the bill at all which related to the conditions of the removal of the medical man from the panel. The statement, therefore, that there was in the bill an extension of the power of the bureaucracy was inaccurate *in toto*. This instance is cited to show the distaste to, or, rather, aversion from, bureaucratic methods in Great Britain and to emphasize the distrust that is evinced by members of the profession to the probable extension of such methods. The profession is aware that its position is weak po-

litically and naturally dreads being under the thumb of one or other of the political parties.

Discontinuance of Sanatorium Benefits Under the National Health Insurance Act, Except in Ireland.—As mentioned in a letter some little time ago, the Minister of Health inserted a clause in the new National Health Insurance Bill whereby tuberculosis was to be removed from the authority of that body and placed under one authority. Lieut. Commander Kenworthy in the House of Commons on May 11, 1920, moved to omit this clause. Dr. Addison, in opposing the amendment, said that in future cases of tuberculosis were to be dealt with by one authority and claimed that the new arrangement would benefit workingmen. It was desired that the treatment of tuberculosis should be extended where necessary. The whole scheme, of which this was designed to be a part, was to secure that one authority was competent to deal with all stages of tuberculosis. It was only proposed to transfer the service from one set of people to another, but it was also proposed that the authorities should have added powers and added funds to perform the service for the benefit of the insured person.

Professor Aldo Castellani Honored.—The President of the French Republic has conferred the title of Officer of the Legion of Honor on Professor Aldo Castellani, C. M. G., of the London School of Tropical Medicine, for his work on combined typhoid-paratyphoid and enteric-cholera vaccination and other scientific investigations which have been found of utility to the Allied Armies during the war.

National Council for Combating Venereal Diseases: Appointment of Traveling Commissions.—The British Colonial Office has invited the National Council for Combating Venereal Diseases to dispatch two commissions, one traveling east and the other west, in order that the benefit of recent eperience gained in Great Britain may be made available in the colonies and dependencies. The commissions will each consist of one medical and one lay member, the former to give postgraduate courses to the local medical faculties under the auspices of the Colonial Medical Services.

Care of the Teeth.—There was held in Manchester, from May 13 to 15, last, an important Congress on Prevention of Diseases of the Teeth, promoted by the Food Education Society. Sir William Milligan, the president, said, in part, that the teeth of Jewish children were superior to those of the Gentiles and suggested that differences of diet might be the cause. Professor Adami compared the teeth of the inhabitants of Great Britain unfavorably with those of Canada, and laid stress on the need for such revision of the Dental Act of 1878 as would ensure that only fully qualified persons should be allowed to practise dentistry. He stated that in his opinion 10,000 additional qualified dentists were required to care properly for the teeth of the country. Dr. Harry Campbell, who is always interesting on the subject of teeth and diet, said that the state of the teeth of the British people, which were the worst of any nation, should excite a feeling of shame and humiliation. At least nine-tenths of this dental disease was preventable. Mr. F. M. Holborn classed pyorrhea aleolaris as the most frequent disease of this country next to dental caries. Tooth-brushing, as generally practised, especially if tooth powders and paste so much in use, were driven under the free margin of the gum, tended to injure the gum at its junction with the teeth. Used in moderation a tooth-brush was harmless, but it should be drawn from the gum towards the teeth to avoid forcing particles beneath the gum. Salt and soap were the safest cleansers. He was in favor of the practice of certain African natives who used a small piece of thin wood to polish the teeth and remove adherent particles. The blind brushing of the teeth from side to side and up and down should be condemned. It may be said that Dr. Campbell was perfectly correct when he said of all the civilized nations, the British possess the unenviable notoriety of having the worst teeth. Professor Adami was also right when he said that Great Britain was lamentably lacking in dentists, and especially in qualified dentists. There are not only an inadequate supply of dentists, but something like two-thirds of the number are unqualified. Although registration of dentists is now law, it will take a considerable time to weed out the incompetent ones. Of course, not all the unqualified men are incompetent, many of them are remarkably skilful mechanically, but the majority of them are ignorant scientifically. On the other hand, some of the qualified dentists are wanting in mechanical skill. The ideal dentist should have both scientific knowledge and mechanical skill. The dentists who should be obliterated are those who advertise blatantly and inveigle the ignorant and gullible. There is somewhat of a reaction, however, against the wholesale extraction of teeth when pyorrhea is present even to a limited extent. As a speaker at the Congress said: "Toothless gums are not natural even to age."

3. Differential Diagnosis of Diseases of the Hip-Joint in Children.—Arthur T. Legg classifies the final diagnosis of 1000 consecutive cases entered at the Children's Hospital out-patient department with a diagnosis of hip-joint trouble, or where the chief complaint has been referred to this joint by the patient. The essential points in the diagnosis of these conditions is brought out by comparison with the symptoms of hip-joint affections, and the difficulties in reaching a correct diagnosis of both. The various conditions with origin remote from the hip-joint which may refer their primary symptoms, accompanied by physical signs, to an affection of this joint, are classified as: Congenital, including dislocation and shortening; nutritional, including scorbutus, rickets, coxa vara and valga, and osteomalacia; nervous, including hysteria, chorea, pseudomuscular hypertrophy; traumatic, including strain,

synovitis, separation of the femoral epiphyses and flattening of the upper femoral epiphysis; extra-articular affections, including bursæ, glands, appendicitis. Pott's disease, infantile paralysis, osteomyelitis, cellulitis, bone abscess, bone cyst, malignant bone tumors, and syphilis, may give rise to symptoms referable to the hip-joint. Affections of the joint itself which the writer discusses include hemophilia, acute infections, and chronic infections. He emphasizes the importance of obtaining a careful history, of making a complete physical examination, of taking a roentgenogram in every case of suspected bone or joint disease, and of utilizing every laboratory method at one's disposal before making a positive diagnosis.

2. The Standardization of Operations for Internal Hemorrhoids.—Louis J. Hirschman, in making a plea for the standardization of operative procedures in the treatment of internal hemorrhoids, reminds the reader that all operative methods are modifications of one of the following types of operation: (1) The ligature; (2) the clamp and cautery; (3) excision with or without ligature; (4) crushing; (5) amputation or so-called Whitehead operation. There are almost as many modifications of these methods as there are operators. All may be performed with either local, general, or spinal anesthesia. In the selection of any operation the following considerations must be taken into account: (1) Safety; (2) removal of all diseased tissue; (3) preservation or restoration of function; (4) minimum traumatization; (5) prevention of hemorrhage; (6) preservation of sphincteric continence; (7) insurance against recurrence; (8) freedom from infection; (9) prevention of pain during and following operation; (10) minimum hospital confinement and detention from ordinary occupation. Hirschman recommends for the standard anesthetic some one of the proved local anesthetics now so commonly used. While the difficulties encountered in an individual case will always govern the variations of technique demanded, the use of the ligature before making an incision is recommended as a standard procedure. Tying before cutting is a principle which not only saves the patient's blood, but presents a much cleaner field for the operation. The general type of operative procedure recommended for a standard operation is excision. A straight elliptical, oval, kite-shaped or dumb-bell wound may be employed, depending upon the amount of diseased tissue to be removed. One should always figure on preserving as much mucous membrane as would normally line the anorectal canal in the region operated upon. The use of sutures as a general rule is not advocated in a standard operation because of the fact that infective material may be imprisoned in the wound with disastrous results. With the proper application of local anesthesia the sphincter relaxes of its own accord to a sufficient extent to allow the removal of the hemorrhoids, and is not insulted by any attempts at manual dilatation or divulsion. If one has been careful to remove all of the diseased tissue below the mucosa and to remove only redundant mucosa, the agglutination of the wounds would be complete in two or three days, if this healing is not prevented by the injudicious use of sutures. For a standard operation the writer recommends the abstinence from the employment of any form of rectal splint, tampon, or packing. There is no indication for the administration of drugs given with a view to inhibit peristalsis. The administration of mineral oil the day following the operation, and daily thereafter, is of much service. With the technique outlined the patient can be on his feet and out of doors as early as the second day, certainly by the fourth or fifth.

4. The Physiology of the Carbonated Brine Baths.—N. Philip Norman sums up the physiological action of the carbonated brine bath in part as follows: There are two thermic stimuli produced at the same time in a carbonated brine bath—a stimulus of warmth to the areas of the skin protected by the gas bubbles and a stimulus of cold to the skin which is in fluid contact with the brine water of the bath. It is possible to give a heart patient a stimulating, cold, carbonated brine bath that will not force the blood out of the skin blood lake. Because of this, the danger of overfilling the abdominal and pulmonary blood lakes is reduced to a minimum. When this overfilling of the abdominal and pulmonary blood lakes occurs, there is a loss of circulatory balance and decompensation is imminent, or in other words, cardiac reserve has been annihilated. The two salts necessary for the brine water are sodium and calcium chloride. When in solution they tend to prevent rapid radiation of heat and aid materially in keeping the water of the bath at a uniform temperature. In addition to this, the chlorides, especially calcium chloride, are irritant in property, to the extent that a permeation of the salts through the epidermal layers of the skin will produce rubifacient action, which persists for some time after the bath and helps to keep open the great skin blood lake. This lessens the resistance to the heart, as there is an equalization of the amount of blood contained in the skin, abdominal, and pulmonary blood lakes. The carbonated brine bath is not complete in its essentials unless the combination of the right proportions of carbonic acid gas, calcium, and sodium chloride is present. A carbonated plain bath does not produce the same effect as a carbonated brine bath. A noncarbonated brine bath is less than useless. The direct action of the carbonated brine bath on the heart is to slow its rate. Since the heart is nourished during diastole or its rest period, anything that slows the heart rate will necessarily increase the rest period, and also increase its nourishment. With increased nourishment and increased removal of waste products and increased rest period the heart is given an opportunity to recuperate and store up a latent force, called cardiac reserve strength, which is of vital necessity to the heart for its proper functioning. With a diminution of peripheral resistance there is a corresponding diminution of cardiac effort which brings about a decrease in the amount of cardiac hypertrophy. Pulmonary circulation is toned up, breathing becomes less difficult, and cyanosis disappears; indeed, in rare instances, according to Norman, a murmur sometimes disappears. Fluoroscopic examinations and orthodiagrams have proved to his satisfaction that cardiac size is actually diminished by a course of carbonated brine baths combined with the resistive exercises.

1. Deficiencies in Our Methods for the Treatment of Chronic Nephritis: Need for Investigation.—Henry A. Christian considers that the treatment of chronic nephritis and associated vascular lesions is handicapped by deficiencies in knowledge as to the etiology and

pathology of these conditions. The treatment, based on such knowledge as is possessed, is largely symptomatic. Preventive treatment is very unsatisfactory. In treating chronic nephritis one aims: (1) To stay the progress of the lesion; (2) to remove edema; (3) to prevent the formation and combat the effects of toxic substances. To stay the progress, one seeks to prevent infections, and by dietary restrictions to decrease renal work and so afford physiologic rest and opportunity for repair. The latter seems a rational procedure, but much knowledge is needed for a basis of determining the optimum for a prolonged intake of water, salt, and protein. To remove edema, the salt and fluid intake is restricted and elimination is increased. Lack of knowledge as to the cause of edema is a handicap in the treatment. Increased elimination by diuretics rarely succeeds when a renal lesion causes edema. Elimination by sweating and catharsis is slow, but may succeed. Mechanical removal is effectual, but temporary. To prevent toxic manifestations, the protein intake is reduced; to combat them, elimination is increased by diuresis, diaphoresis, catharsis, and bleeding. Bleeding is the promptest and most effectual method of elimination of toxic substances.

1. **Neonatal Mortality.**—Sir Arthur Newsholme holds that among the outstanding events in the medico-sociological history of the last fifty years a foremost position must be given to the steady decline of the birth rate, which has occurred in most civilized countries, and to the increased attention devoted to the welfare of infants and their mothers. In view of the commonly entertained error that infant mortality may, on the balance, be selective in character, securing survival of the more robust, it is noteworthy that the parts of England which have the highest infant mortality continue at higher ages to experience a higher death rate than more favored districts. Any possible elimination of the weakest by natural selection which may have occurred is accompanied to a preponderant extent by the manufacture of weaklings and by an excessive death rate at older ages, due to continuance throughout the whole of life of the evil conditions which caused the excessive infant mortality. From the economic standpoint attack on infant mortality offers abundant scope for action. Here is a period representing about one-eightieth part of the whole life; but in this period one out of nine or ten total deaths occur; furthermore, the state of health in infancy in large measure determines the health standard of the whole of life. From the same standpoint the mortality under one month, first described by Ballantyne as neonatal mortality, also is especially important. At least one-tenth of the total deaths at all ages occur in infancy; one-half of these infantile deaths occur within the first three months, one-third within the first month, and one-fifth within the first week after live birth. If, therefore, it were practicable to halve these early or neonatal deaths a greater saving of life could be obtained than by halving the death rate at any other period of life of equal length. This early infant mortality is in large measure preventable. Accepting the view that infants do not "start fair" at birth, and giving the reasons for this inequality, Sir Arthur proceeds to discuss the prevention of neo-natal mortality along the following lines: (1) Need for continuity of supervision; (2) ante- and post-natal clinics; (3) skilled care during parturition; (4) provision of maternity homes and hospitals; (5) raised standard of midwifery practice throughout the country; (6) the need for further research in ante-natal pathology.

1. **A Clinical Lecture on Chronic Paroxysmal Trigeminal Neuralgia and Its Treatment.**—Wilfred Harris, discussing the treatment of this condition, states that only a comparatively small number of sufferers get relief from drugs. In a few gelsemium gives relief, though with the majority even morphine in large doses fails. Practically the only two methods are gasserectomy and alcohol injection. In the writer's opinion the former operation should never be undertaken until alcohol injection has been thoroughly tried. During the last ten years he has injected the Gasserian ganglion with alcohol through the foramen ovale in sixty-three cases. In thirty-one the anesthesia has remained total and no recurrence of pain has taken place. In the remainder partial ganglion anesthesia has persisted, though pressure could be felt, yet the relief from pain appears to be equally good. In many cases, though total ganglion anesthesia is produced at the time of the injection, yet the anesthesia of the first and second divisions wears off, perhaps completely, in from ten minutes to an hour, though the third division remains totally anesthetic. This, it is held, is no doubt due to the ganglion cells having been shocked, and not destroyed, by a partial infiltration only. In such a case pain is liable to recur after twelve months or two years, as in a case of ordinary injection of the nerve. With total destruction of the ganglion there is the same liability to keratitis as with the operation of gasserectomy, but if the lids are kept carefully closed by strapping for the first week and the conjunctival sac washed out with boracic lotion twice a day, little or no trouble will be experienced. The lids, however, should be kept closed from the beginning, and it is unwise to wait and see whether keratitis develops, as then it will be necessary to keep them closed for a much longer time. Hutchinson's partial gasserectomy avoids the danger of keratitis, but it is not a certain permanent cure. Harris emphasizes the importance, in connection with the injection of alcohol, of using the method of trial and test. That is to say, when the needle is thought to have struck the nerve inject a few drops of 2 per cent. novocain, and, after waiting half a minute, test the skin distribution of the nerve for anesthesia. If none has developed do not inject alcohol, but try again to find the nerve. As soon as anesthesia appears to novocain injection, then complete by injecting about one cubic centimeter of 90 per cent. alcohol, when total anesthesia to touch, pin, and pressure will develop almost instantaneously if the nerve at the foramen ovale or foramen rotundum has been correctly hit. In almost every case, as soon as anesthesia develops from the injection the neuralgic spasms cease, and they can no longer be started by any chewing movements or rubbing the face. The duration of the cure rarely lasts less than twelve months, if good anesthesia has been obtained, and in the majority the relief from pain lasts from two to three years. Many of the writer's cases have been quite

free for four or five years, one six and a half years, another seven years, another nine years after nerve injection only, while he expects his cases of ganglion injection to be permanent cures, just as if gasserectomy had been done. No trophic effects on the skin are ever seen. Keratitis is a risk if the cornea is anesthetic after injection of the ganglion, but this may always be avoided by proper precautions.

Schweizerische medizinische Wochenschrift.

April 8, 1920, i, 15.

Influenza in Switzerland in 1920.—Professor Eichhorst describes the epidemic of grippe which has prevailed in Zürich during the present winter. In his opinion it can only be an echo of the pandemic of 1918-19. In the first place the history of influenza epidemics is full of these recrudescences. Second, there is no evidence that it has been imported from any point outside of Switzerland—although with the great movement of people in and out of the country such a contingency has favored importation. But there is nothing really to explain in the recrudescence. At the beginning of January there was a sudden increase in the preceding number of grippe cases. The weather was characterized by cold and fog—a fact of no apparent significance, for the great pandemic began in hot, dry weather. In detail, during the second week in January a woman with grippe bronchitis entered the medical clinic and was quickly followed by two other cases. By February 4 the total number was 150, and up to February 22 another 309 were added, making a total of 459 cases in 46 days, or almost exactly ten a day. The summit of the wave had, however, been passed, the disease rapidly abated, and the further incidence is not important. Women predominated, as in the great pandemic, but not to such an extent. There seemed to be an unusual incidence in working girls who came much in contact with travelers—shop girls and hotel servants. As during the pandemic, there was a tendency for the adults to suffer rather than the children and old people, although the line was not so closely drawn as in the former episode. Of the 459 cases there were 236 of bronchitis, 148 of grippe pneumonia, and 53 of grippe sepsis. The total number of deaths was 40, with a mortality of 8.7 per cent. Under grippe sepsis the author includes cases with rashes, joint pains, etc. Of special interest were 14 cases of grippe encephalitis with 11 deaths. There was one stuporous case, not included under lethargic encephalitis. Other cases showed a variety of motor disorders—jactitation, choreatic movements, epileptiform attacks, etc. There were also delirium and maniacal behavior and actual meningitis. At the same time there were cases of encephalitis lethargica in the clinic, and the author makes no attempt to discriminate radically between these and the grippe cases. But one case of ocular paralysis is mentioned.

Lo Sperimentale.

March 31, 1920, lxxiii, 5-6.

New Developments of Our Knowledge of Typhus.—Ferrari believes in the great antiquity of typhus—it was the "pest" of the classic epoch and was the malady described by Cyprian, Bishop of Carthage, in 253 A. D. Its first magistral description was by Fracastor of Verona. Diffused everywhere, it became endemic in certain countries, as Ireland, Russia, and the Balkans. It was responsible for Napoleon's overthrow and for the defeat of Russia in the Crimean War. We have gradually learned the part played by the clothes louse in its transmission, and recently it has been shown that the pediculus capitis and pediculus pubis are able to transmit it, although they play but a small part here. No other insect or sensible parasite has been successfully accused of transmission thus far. In regard to the actual cause of the malady, the author devotes the greater part of his space to the Rickettsia, other organisms being summed up briefly in fine print with the exception of the proteus vulgaris, and this, on account of the importance of the Weil-Felix reaction, receives a full discussion. Naturally, its specificity is not admitted. The anatomical vascular changes described in the skin by Fraenkel are also said to be present elsewhere in the body, not only in man, but in infected laboratory animals. Aside from the anti-louse measures, the most pressing need at present is a vaccine to protect nurses and other attendants if the former measures fall short. The use by several Turkish physicians of the defibrinated blood of victims for this purpose to secure immunity has been followed by the similar use of blood serum, and in the hands of Nicolle this has given good results, while whole blood used as control proved negative. This resource is therefore our principal hope for the future.

Norsk Magazin for Laegevidenskaben.

April, 1920, lxxxi, 4.

Diabetes and Influenza.—Motzfeldt states that during the pandemic of 1889-90 diabetes was a not infrequent association. The recent pandemic, however, does not thus far appear to have shown the latter, but this may be due to the neglect of reporters. The author saw four cases of diabetes which were first apparent during the influenza. The patients were all young, ranging from fourteen to thirty-five years, two being practically children—under the age of sixteen. Despite this fact, the type of diabetes was very mild. In three of the cases carbohydrate tolerance increased under treatment. The case in the man of thirty-five was of special interest. During the progress of the influenza this patient felt a deep epigastric pain, which was followed by thirst and polyuria after the fever had ceased or during convalescence. He was not interned for a month afterward, when the urine gave a positive ferric chloride reaction. The sugar disappeared after five days of treatment. Eighteen months later the carbohydrate tolerance was tested and 500 gms. bread could be ingested without glycosuria. But after the ingestion of fifty gms. pure glucose glycosuria appeared and lasted three hours. The case was thought to have been an influenzal pancreatitis.

Blindness After Ingestion of Methyl Alcohol.—Harboe relates the case of a postman who on a certain day in August, 1919, drank ten gms. of methyl alcohol mixed with water. Soon afterward acute poisoning set in. Visual troubles which appeared at this time culminated in complete blindness three days later. Seven days after this episode he entered the hospital and the right eye could only count fingers at half a meter off, while the left eye beheld the screening of a light 20 cm. off. Externally and to the mirror the eyes were intact. During a prolonged sojourn in the hospital he had regained vision to some extent, without having reached the normal standard. Some optic nerve atrophy was apparent. Vision of the right eye was 5/7.5, and that of the left 5/20, corrected with lenses.

Nursing in Poland.—Learning a lesson from war experience, Poland, along with other European countries, is beginning to follow the lead of England and America in the matter of developing a trained nursing personnel. There are now in Poland more than fifty Polish Nurses' Aides who are studying in various hospitals under American direction. When Lieutenant-Colonel Chesley, American Red Cross Commissioner to Poland, called for thirty volunteers for a beginner's class, over a hundred and fifty applicants responded, and these beginners are now receiving preliminary training from the chief nurse. It is in this eastern field of the war, where fighting still goes on, and where thousands of sick and hungry refugees are making their way back home from their exile in Russia, that the need of nurses and modern nursing methods in most felt at the present time. "The suffering and deaths that have occurred in this locality have emphasized the great shortage of nurses," says Mrs. Jokaitis, chief nurse of the Red Cross. "But the Polish doctors have no foolish ideas about women. They are all for modern ideas." Indeed, the enthusiasm of the Poles over American ideas is unbounded, and the speed with which Polish girls of the best type are being recruited for the work is extremely encouraging. "I wouldn't be surprised to see Poland become the center of woman's activity in Europe," commented Mrs. Jokaitis. "This country gives promise, in many ways, of being a 'second America' once she gets on her feet. And the women of Poland will have a big share in getting her there."

Book Reviews.

THE PRINCIPLES OF ANATOMY AS SEEN IN THE HAND. By FREDERIC WOOD JONES, D.Sc., M.B., B.S. Lond. Professor of Anatomy in the University of Adelaide; Sometime Professor of Anatomy in the University of London, at the School of Medicine for Women; Examiner in Anatomy to the University of London, the Conjoint Board of the Royal College of Physicians and Surgeons, and to the Society of Apothecaries. With two plates and 123 Text figures. Philadelphia: P. Blakiston's Son & Co., 1920.

THIS is a most interesting book and it should strongly appeal to all practitioners of medicine and surgery. It is about as far removed from the ordinary textbook on anatomy as one can imagine. The author does not omit any necessary anatomical details, but he presents his facts in such a way that he makes an interesting and connected whole, and he carefully refrains from haggling over unnecessary trivialities. The work has a philosophical trend; the reader's attention is held from the first page to the last; and, just now, the chapters dealing with the muscles of the hand and their action are of special value, and should be studied by those who are interested in re-educational work. As a textbook and for examination purposes the book is valueless, but for creating a real interest in anatomical study this work ranks with such classics as Holden's Osteology and Treves' Surgical Applied Anatomy.

FESTSTELLUNG UND BEHANDLUNG DER TUBERKULÖSEN INFEKTION MITTELS ANTITOXISCHER HEILKÖRPER. By Dr. EMANUEL WEIN. Berlin and Vienna: Urban & Schwarzenberg, 1918.

THIS work, which appears in three parts, comprising altogether 608 pages, discusses the determination and treatment of tuberculous infection with the aid of antitoxic substances and has a rather tragic history. It was begun by Dr. Emanuel Wein in 1909, and was ready for publication at the outbreak of the war in 1914. According to the preface by Dr. Zoltan Wein, who has now succeeded in having the book published as the posthumous work of his father, it was out of the question to have it appear at the time when it was completed; times were too hard, too unsettled.

Emanuel Wein was an enthusiast and a strong believer in the possibility of treating tuberculosis by specific antitoxic remedies. In this volume he describes in detail the effect of the isopathic remedies, that is to say, the various tuberculins and the effects of the antitoxic products, such as Marmorek's serum and Spengler's I.K. (Immune Körper). It would not be possible here to enter at length into a discussion of the author's views and results of experiments with tuberculin and antitoxic remedies. He comes to the conclusion that the diagnostic value of tuberculins is much greater than generally recognized, that wrong etiological deduction is the reason that the specific remedies do not receive sufficient consideration, that the specific curative qualities of the antitoxic means, such as Marmorek's serum and Spengler's I.K., can no longer be doubted, that a few doses of Marmorek's serum or Spengler's I.K., carefully administered, will remove all doubts whether the disease has been caused by or was simply influenced by a tuberculous infection. He claims that Marmorek's serum and Spengler's I.K. only affect diseases due to Koch's bacillus of tuberculosis. Careful instructions are given for the administration and indication of the two remedies referred to. Wein believes that many diseases concerning whose etiology we are still in doubt, such as digestive disturbances in infants, obscure fevers and nervous manifestations in childhood, skin affections, migraine, incontinence of urine, dysmenorrhea, and many other affections, in the vast majority of cases are due to tuberculous infection and are amenable to treatment by specific medication.

Even if one is not an enthusiast about the use of culture products as a means for diagnosis or as remedial agents in tuberculosis, one cannot help admiring the author's painstaking experiments and clinical researches. He admits that immunization has, up to this time, been a failure, but maintains that with tuberculin and Marmorek's serum we are in the possession of agents of great help for an absolute diagnosis and that with Marmorek's serum as well as Spengler's I.K. we have remedial agents at our disposal with which tuberculosis can be cured. While in the reviewer's opinion many of Wein's claims need further substantiation, the author's statements, borne out by the citation of 100 cases, that many diseases not diagnosed as tuberculous are due to or influenced by a tuberculous infection, merit our study and consideration. The volume as a whole is well worth the most careful persual of all interested in tuberculous research work.

DISEASES OF WOMEN, Including Abnormalities of Pregnancy, Labor, and Puerperium. A Clinical Study of Pathological Conditions Characteristic of the Five Periods of Woman's Life, Presented in One Hundred and Seventy-three Case Histories. By CHARLES M. GREEN, A.B., M.D., Professor of Obstetrics and Gynecology, Emeritus, in Harvard University; Senior Surgeon for Diseases of Women, Boston City Hospital; Formerly Visiting Physician, Boston Lying-in Hospital; Fellow of the American College of Surgeons; Fellow of the American Gynecological Society. With 12 full-page Plates, one Cut, and 25 Charts in the Text. Boston: W. M. Leonard, 1920.

ALTHOUGH not so stated in the title-page, this is the second edition of this work, the first having been published five years ago. The changes made in this edition are not very numerous, yet are important and add to the value of the work. The book is one of the "Case History Series," in which the method of teaching is purely clinical and therefore most interesting and instructive for a reader who is already familiar with the general principles of the subject. Dr. Green divides the life of women into five stages, viz., infancy and childhood, puberty and adolescence, maturity, the climacteric, and old age, and illustrates the diseases and morbid states peculiar to these stages with a number of well told histories followed by explanatory comments. Any recent graduate with a bent toward gynecology, or even aiming only for general practice, will be amply repaid by a careful reading and study of this book.

MEDIZINISCHE TERMINOLOGIE, Ableitung und Esklärung der gebraüchlichsten Fachausdrücke aller Zweize der Medizin und ihrer Hilfswissenschaften. Von WALTER GUTTMANN, Oberstabsanzt z.D. an der Kaiser-Wilhelm-Akademie für das militärärztliche Bildungswesen in Berlin. Zehrite und elfte vollkommen ungearbeitete Auflage, mit 309 Abbildungen. Berlin and Wien: Urban & Schwarzenberg, 1919.

THIS is the combined tenth and eleventh revisions of Guttmann's medical dictionary, the standard and best work of the kind in the German language, a separate tenth edition having probably been prevented by war conditions. That the present revision is up to date is shown by the inclusion of a number of terms created by war conditions, such as the Carrel-Dakin method, hunger disease, etc. For all who read much German medical literature, this capital dictionary will be found of the greatest service.

APHASIA AND ASSOCIATED SPEECH PROBLEMS. By MICHAEL OSNATO, M.D., Associate in Neurology, Columbia University; Consulting Physician, Manhattan State Hospital and Central Islip State Hospital; Neurologist, Italian Hospital; Assistant Visiting Physician, Kings County Hospital; Assistant Chief of Clinic, Vanderbilt Clinic Department of Neurology. Preface by FREDERICK TILNEY, M.D., Ph.D., Professor of Neurology, Columbia University. New York: Paul B. Hoeber, 1920.

THIS is a valuable little volume in that it is a vigorous and not wholly unsuccessful attempt to present clearly the essentials of an intricate and highly controversial subject. The usual tendency of the student of aphasia is either to become confused among the available theories or to become too partisan. Dr. Osnato has presented the various viewpoints clearly and simply, indicating their virtues and faults. His own presentation of the subject might be called a psychological one, *i.e.* he considers aphasia as largely symptomatic of or dependent upon intellectual defects. From his wide experience Dr. Osnato has selected a number of apposite cases; and at the end of the book he quotes most of the recent worth-while literature.

Society Reports.

AMERICAN ASSOCIATION FOR THORACIC SURGERY.

Second Annual Meeting Held in Atlantic City, N. J., June 9, 1919.

(*Concluded from page* 1062.)

THE PRESIDENT, DR. WILLY MEYER OF NEW YORK, IN THE CHAIR.

IV. Anterior Mediastinum: The Treatment of Malignant Tumors of the Thymus by Radium.—Dr. HENRY H. JANEWAY of New York based this paper upon a report of 9 cases in which a diagnosis was confirmed by microscopic examination in 6 of the 9 cases. In the 3 remaining cases favorable cures, lasting for a period of over two years, had followed the radium treatment.

Dr. EMIL G. BECK of Chicago, Ill., referring to Dr. Janeway's pictures, said these shadows were often misleading; the arch of the aorta might be mistaken for a tumor. One could select many of the plates which showed that in a series of cases. However, one relied upon the symptoms which pointed to the tumors. Radium had a great place in the treatment of these intrathoracic tumors. The tumors might be four or five times this size and would disappear, not alone by radium treatment, but also by *x*-ray. Hodgkin's disease also would disappear. There were tumors which on proper treatment by deep therapy would disappear and as soon as the treatment was discontinued would reappear. The patients invariably died ultimately of the disease. He had had three such cases. In these cases good stereoscopic pictures should be taken, for they would give a great deal more information. In that way one could see whether the tumor was anterior or posterior, or whether connected with the aorta. Sometimes aneurysm would give such a picture. In the last three years he had used *x*-ray in such tumors, recurrent carcinoma of the breast, neck and other places. The recurrence had taken place after two or three operations. After three radical operations had been performed in one of the cases the patient was subjected to a fourth operation, and in that case the skin and fat was removed and the entire area was exposed for *x*-ray directly on the open wound. The skin filtered as much as three-fifths of a mm. of aluminum. He had proved that by electrocopic measurements the skin absorbed nearly all of the beta rays. The beta rays were very important in the radium as well as the hard rays of the *x*-ray treatment.

Dr. Janeway, in closing the discussion, said he had stereoscopic pictures made, and the shadows of the tumor were anterior to the arch.

V. Diaphragm: Roentgenographic Study of the Diaphragm After Intraabdominal Inflation with Oxygen. Preliminary Report. (Lantern Slides.)—Dr. WILLIAM H. STEWART, in conjunction with Dr. ARTHUR STEIN of New York, presented this paper. They had been stimulated to make this investigation by an experience with a case of gunshot wound of the chest. In localizing the bullet, great difficulty was encountered in ascertaining whether the projectile was in the diaphragm, beneath the diaphragm or in the lower lobe of the lung. The case was reported by Dr. Meyer before the New York Society for Thoracic Surgery, and in the discussion Dr. Howard Lilienthal suggested that they could rule out the question of the bullet being in the lower lobe of the lung by producing an artificial pneumothorax; if in the lung it would recede from the diaphragm with the pulmonary collapse. If this could be done, they saw no reason why a pneumoperitoneum would not produce a separation of the liver from the diaphragm, thus enabling one to decide whether the bullet was in the diaphragm or beneath, embedded in the liver. Dr. Arthur Stein had called their attention to an article by Dr. C. Goetze, published in the *Münch. med. Wochenschift* for November. 1918, suggesting roentgenographic examination after the inflation of the peritoneal cavity with oxygen to bring out the detail of the abdominal soft parts. They were familiar with the fact that in the presence of air or gas much more roentgenographic detail of the soft parts could be obtained than under ordinary conditions, and had taken advantage of this phenomena in cases of soft growths of the bladder by inflating the viscus with air. Artificial pneumothorax had been used to obtain pleural detail where there was a question of malignancy of the pleura, and the ventricles had been clearly demonstrated in a case of fracture of the skull, where the brain cavities had become inflated with air through an opening in the soft structures at the site of the fracture. With these experiences in mind, and with the support of Dr. Stein, who had inflated all of the cases in the series, he had begun the investigations. The results, as shown by the lantern slides, were somewhat startling. They had been able to obtain clear detail of the liver and spleen, and had found that these organs were distinctly separated from the diaphragm, thus proving the value of the method in localizing projectiles or inflammatory conditions beneath the diaphragm. In addition they had learned that clear shadows of the other abdominal organs could be obtained such as the kidneys and pelvic organs. Intraperitoneal adhesions were easily shown, and in one case a chain of enlarged mesenteric glands were demonstrated. It was evident that a new field for investigation had been opened, especially in obscure abdominal cases, where the pathology involved the parenchymatous organs. The technique employed was most simple. After the patient had been prepared for roentgen examination by a cleansing out of the bowels and emptying of the bladder, he was put upon his back, and the abdomen was inflated with three to four liters of oxygen. The whole outfit required for this precedure consisted of an oxygen tank to which was attached a rubber bag, such as was used with gas-oxygen apparatus for anesthesia, with a capacity of about one gallon or four liters. To this bag was attached a small rubber tube which could be easily connected with a regular lumbar puncture needle. The spot where the needle was to be inserted was sterilized with iodine, and the skin was rendered insensate by an injection of novocain-adrenalin solution. The spot from which, in their judgment, it was easiest to inflate the abdomen was two or three fingers to the left of the umbilicus, and about one and a half inches below it. One who has had surgical experience can easily gauge the thickness of the abdominal wall. Their practice had been to push the needle to a point where it touched the fascia, then to stop for one or two seconds. After that the necdle was pushed gently through the fascia, muscle and peritoneum. The plug was then removed from the needle, and the needle connected with the rubber tube. A slight pressure on the bag would now inflate the abdomen with oxygen. As a rule, this required between four and five minutes. The amount of oxygen to be introduced varied with the condition of the abdominal walls; a fair amount of distention should be obtained, enough so that the abdominal wall was put somewhat on a tension, and had more or less of a dome shape. When the peritoneal cavity was fully distended the patient usually complained of a sensation of fulness and slight pains in the shoulders, particularly the right, apparently due to pressure against the diaphragm. If there was a possibility of abdominal adhesion being present as shown by an abdominal scar one should select his point of entrance for the needle as far from the operative site as possible. The oxygen, as a rule, was absorbed within 24 to 48 hours, So far they had had absolutely no ill effects, the danger of puncturing the intestines was nil. Experience had shown that the elasticity of the intestines permitted them to recede before a sharp introducing body, such as a needle, providing caution were used and the needle advanced slowly. It was best to allow the patient to become accustomed to the distention before attempting the roentgenographic examination, usually an interval of two to three hours being advisable, at which time it was possible to place the patient in almost any position without distress. The main point to bear in mind in the roentgen technique was that the organ to be investigated should be elevated as much as possible. The spleen and left kidney were best brought out with the patient lying

on the right side, the liver and right kidney the reverse. The pelvic organs with a lateral Trendelenburg position, and intraperitoneal adhesions with the patient lying on his back.

Dr. CHARLES G. HEYD of New York had been in the habit of introducing a needle a little to the left of the ensiform cartilage and at its lower level with the patient in the sitting position. The needle entered readily and there was practically no danger of injuring any of the viscera.

Dr. NATHAN W. GREEN of New York referred to certain animal experimentation at the College of Physicians and Surgeon. Dr. William C. Clarke was speaking of the danger of perforating the intestines when doing an abdominal puncture. He took a rabbit and placing it under anesthesia, put in a fine needle. While the rabbit was alive the intestines were pushed away by the needle. The rabbit was then given a lethal dose of ether. When it was dead the needle would go right into the intestines.

Dr. WILLY MEYER of New York cited briefly the case referred to by Dr. Stewart of a male, shot in the sixth intercostal space on the right side. No special symptoms; brought to a hospital; some bloody expectoration; cured. Bullet found by *x*-rays. After some time the patient was sent to him to determine whether the bullet should be removed or not. As it seemed to be in the right lower lung lobe it was decided to attempt its removal. Dr. Stewart repeatedly examined the patient with *x*-rays and the fluoroscope. It was impossible to say whether the missile was surely in the lower portion of the right lung, or in the diaphragm, or in the liver! Direction and point of entrance of the bullet as well as location was such that they had to go through the thoracic cavity. If the method of examination just presented had been employed, a definite localization would have been possible. They would not have been annoyed by sudden developments during the operation. They would have known that the bullet was in the convexity of the liver. The method seemed to mean a great step forward in the refinement of diagnosis with reference to the intra-abdominal organs.

VI. Lungs: **1. The Integrity of the Vagus Nerves as a Factor in Pneumonia.**—Dr. SAMUEL J. MELTZER of New York said that since Galen's time many experiments had been made on the effect of cutting both vagus nerves upon the animal. In the eighteenth century it had been recognized for the first time by Valsalva and Morgagni that the lungs become affected after both vagi are cut. They had simply stated that there was an alteration in the lungs. But this alteration had soon been recognized as being an inflammation. Numerous experiments followed. In the middle of the nineteenth century the question seemed to have been settled by the experiments of Traube, who was the first to establish that the cutting of both vague nerves caused aspiration pneumonia. According to Traube the pneumonic lesions of the lung, which appeared one of two days after section of both vagi were brought about by a paralysis of the esophagus and of the muscles which control the movements of the glottis; these paralyses facilitated the entrance into the trachea and the lungs of the contents of the esophagus and of saliva. Schiff looked upon the ensuing pneumonia as neuroparalytic in its origin. According to Traube the states of the blood vessels and of the tissues of the lung were not primary causes of the pulmonary lesions. Traube's view was one which prevailed to this date. All investigators had agreed that cutting of one vagus produced no affect at all. In the course of the last eight years Dr. Woolstein and the speaker had studied extensively the causation of pneumonia by intrabronchial insufflation of cultures of different organisms of various degrees of virulence. Since August, 1918, they had studied a new problems by the same method. Virulent cultures of pneumococcus Type I were insufflated several days after a single vagus was cut. Their main results were very briefly stated. If the injection of the culture was made only four days after the section of the vagus the course of the development of a pneumonia was the same as in normal animals. But if the injection was made ten or twelve days after the vagus was sectioned most animals died in less than twenty-four hours, the nature of the pulmonary lesion being that of red hepatization. He would not enter into an extensive discussion of their possible significance, but would recall some physiological facts. Vasomotor fibres consisted of vasoconstrictors and vasodilators. If vasomotor nerves were cut the vasoconstrictors degenerated four days after cutting, while the vasodilators degenerated only ten or twelve days after cutting. Putting together the new facts regarding the rapid development of experimental pneumonia instituted ten or twelve days after the cutting of one vagus nerve (but not when instituted earlier) with the known facts regarding the rate of the degeneration of the two sets of vasomotor fibres, hypothesis seemed to be plausible that resistance of the lung tissue to infection depended, among others, upon the integrity of the vasodilator nerves of the lungs. But one must keep in mind that it was still a moot question whether the pulmonary circulation was altogether under vasomotor nerve control. Dr. Meltzer added that he had reported some facts and offered an hypothesis for their explanation. He wished to emphasize that he was mostly interested in the facts; they were fundamental, and he thought they would stand the test. As to the hypothesis, he was aware that what he had said was not the last word. He himself could offer other explanations; but he did not intend to enter into a lengthy theoretical discussion.

Dr. WILLY MEYER of New York asked Dr. Meltzer whether he thought mechanical interference with the nervi vagi during operation, as stretching, tearing branches, etc., as one often could not help doing, might also have the effect of making the lung more inclined to inflammation. He ventured to put this question, because anyone who did surgery on the esophagus would observe that if one were fortunate enough to pull these patients through the operation and the first days of the after treatment, they were very liable to be stricken with pneumonia further on. His question was, whether Dr. Meltzer thought the mechanical interference with the pneumogastrics, according to his opinion, was just as much inclined to produce pneumonia as the resection of their main trunk.

Dr. MELTZER replying, said the president had spoken of the dangers of the handling or tearing of a vagus nerve. They had tested that problem in the laboratory. Under efficient artificial respiration even rough handling of the vagus nerve had no evil consequences. The heart might be manipulated practically with impunity. It was different when insufficient artificial respiration was employed. The heart might fall into fibrillary contractions at the slightest provocation and stimulation of a vagus nerve was indeed not an innocent procedure. These facts had been frequently demonstrated to the hundreds of military officers who were commanded during the war period to the Rockefeller Institute. Differential pressure offered only an inefficient artificial respiration. The animal or the patient might stand even a long operation under its protection; but heart and nerves must be handled with great care. Auer and the speaker had reported these facts some eight years ago. Quite recently Giertz of the physiological laboratory in Stockholm had arrived at the same conclusion.

Dr. MEYER said if one went over the literature and also turned back the leaves in one's own memory, the fact would stand out that sometimes cases that one believed would recover, had died of pneumonia in the second week after the operation. And it was further a fact that one could not operate on a case of advanced cancer of the esophagus without being obliged to tear one or more larger branches and later on often cut the entire trunk of the pneumogastric, or of both. Only recently he again made the observation in such a case, a female, that pneumonia took her away on the thirteenth day. He knew definitely that one pneumogastric had been much interfered with. He had attributed the cause of the fatal issue to the interference with the pneumogastric. It certainly seemed to be a clinical fact that the partial or complete resection of one pneumogastric made the patients prone to catch pneumonia.

2. Localization of Pulmonary Lobes by the X-Ray.—MAJOR KENNON DUNHAM of Cincinnati, Ohio, read this paper. (See page 1077.)

3. Lung Abscess.—Dr. NATHAN W. GREEN of New York, in writing of the diagnosis of lung abscesses, stated that the presence of a subacute abscess might be suspected when, after pneumonia or empyema, the temperature came to normal and then rose and was accompanied by a hacking cough and a fresh appearance of pus in the sputum. In chronic lung abscess the patient might appear chronically ill or in fairly good condition except for local symptoms. The chief symptom was a profuse and characteristically foul expectoration, the amount of which varied with change of posture and at different periods of the day. The *x*-ray was an aid to the diagnosis. There was always a cough, generally a slight evening temperature, and a certain amount of anorexia. The physical signs were often obscure and of themselves might not lead to a diagnosis of abscess. Generally they were those of localized consolidation with occasionally cavernous breathing. Clubbing of the fingers was a constant concomitant as in bronchiectasis. The sputum was greenish yellow. The treatment was medical and surgical. Medicines might be given to decrease and deodorize the sputum. Posture might improve the condition. In ambulatory cases, standing on the hands might me beneficial. The surgical treatment consisted of thoracotomy with resection of one or more ribs and evacuation and drainage of the abscess. The author did not believe that artificial pneumothorax could be of benefit uniformly because the spot which it was desired to collapse was kept out, being fastened by adhesions to the parietal pleura. Certain lung abscesses with thickened walls might require more extensive surgical treatment than simple drainage. Resection of a lobe might be necessary. When an operation was performed to drain the lung abscess it might be done in one, two or more stages. The first stage would indicate the patient's power of resistance.

4. Pulmonary Suppurations.—Dr. CARL A. HEDBLOM of Rochester, Minn., presented this paper. (See MEDICAL RECORD, September 13, 1919, xcvi, 11.)

5. Resection of the Lung for Post-Tonsillectomy Abscess.—Dr. HOWARD LILIENTHAL of New York presented a patient in whom extirpation of the lower lobe, the middle lobe, and part of the upper lobe of the right lung was followed by atrophy which left no lung in the right chest. Fifteen months after a tonsillectomy the patient had first shown chest symptoms, cough, hemorrhages, and foul expectoration, which had been followed by intermittent periods of fever, coughing, and the discharge of large quantities of fetid pus. *X*-ray examination of the chest had demonstrated a cavity of the right lung in the midclavicular line and an area of infiltration from the seventh to the ninth rib. There was much infiltration into the lung tissue outside the zone of inflammatory reaction. Under intrapharyngeal gas and ether anesthesia, a long incision was made in the seventh interspace, the greater part of the seventh rib resected, and the sixth rib sectioned posteriorly. Adhesions were then separated and all fluid was removed. A large abscess was found between the upper and middle lobes. The lower and middle lobes and part of the upper were then ablated beyond mass ligatures of chromic gut and heavy silk. During this procedure pus appeared at the patient's mouth. After the removal of the major portion of the lung the stump was carbolized and the transfixing ligatures were fixed outside the chest to prevent mediastinal motility. A large quantity of fluff gauze was packed about the stump and the wound closed without drainage, the packing and ligatures being buried beneath the skin so that at the end of the operation the chest was completely sealed. Before the last suture was tied more than a pint of paraffin oil was poured into the chest and left there. Later the wound was reopened, a drainage tube inserted and about a quart of foul fluid evacuated. The wound was then opened wide because of infection and sloughing, but due to the open bronchi it was impossible to use Dakin's solution. The case now showing all the evidence of gangrenous pleurisy, the entire chest cavity was packed with gauze, a procedure which was followed by improvement in the local condition. Later the right phrenic nerve was resected to paralyze the diaphragm but the subsequent *x*-ray showed that this muscle was already held down by adhesions. The eighth, ninth and tenth ribs were then resected to aid in collapsing the lower chest. At the end of four months the patient returned to work. Complete closure of the chest took place after a year. At that time *x*-ray showed no evidence of lung tissue in the periphery of the entire right side, but a partially aerated lung field was observed at the hilus.

6. The Operative Treatment of Advanced Pulmonary Tuberculosis.—Dr. WILLY MEYER of New York pointed out the great progress made in the treament of this chronic disease by the application of the artificial (therapeutic) pneumothorax. However, he asked, what was to be done if the lung was fixed to the chest wall by adhesions. If medicinal and hygienic treatment did not improve these patients, they were doomed. It was here that active surgery had stepped in since the last ten years. By means of extrapleural thoracoplasty one was able to completely collapse the respective lung. The effect was easy to understand. As soon as the parts of the thoracic skeleton to which the adherent lung was attached, were removed, it would collapse. The operation could be nicely done under regional and local anesthesia by nerve blocking, best with Sauerbruch's hook incision, which represented the posterior half of the original Schede incision. Other operative measures were: the one first used by the late Friedrich, Schede's incision and immediate removal of the tenth to the second rib in one stage, and Wilms' socalled columnar-resection, consisting in removal of a portion of the ribs, anteriorly and posteriorly, the middle part being used for collapse and compression. Sauerbruch feared aspiration from a cavity in the upper lobe, if the entire work was done in one stage and, therefore, proposed a two-stage operation, resecting the tenth to sixth rib in the first stage, and a few weeks later, the fifth to second or first. Wilms did not share this fear. Further investigations were required to determine whether it was justified or not. The results in the series of cases published by Friedrich, Sauerbruch and Wilms independently of one another, were almost the same, and very encouraging. Two-thirds of these otherwise entirely hopeless cases, were either improved, greatly improved or cured by operation. Unilateral tuberculous lung disease, particularly *with cavity formation*, represented the most favorable lesion for this operation. Still, it had proved useful also in cases in which the opposite lung was also somewhat involved. The speaker presented a patient of 31 years, in whom he had done extrapleural thoracoplasty in two stages, under local anesthesia. The trouble was bilateral, particularly pronounced on the left side. At the present time, six months after the operation, the patient was very greatly improved; his sputum was markedly reduced and free from bacilli; the cough had almost completely disappeared; he had considerably gained in weight.

Dr. EMIL BECK of Chicago, Ill., considered these last two cases so instructive that they would encourage a great many to enter into this work, because the material was plentiful. The question arose as to which of the two operations would be preferable. Excision of the lung seemed to him a formidable operation. It was probable that both of these patients would have been better if they had not been operated upon. The diagnosis of lung abscess was very easy, but it was more difficult to cure than to diagnose. The abscess was usually centrally located and much smaller than empyema. In his opinion every lung abscess that was diagnosed should not be operated upon. He had refused to operate in three cases for the reason that the abscess was rather inaccessible. Sometimes the patient was much better off after the abscess had ruptured into the bronchus. He might be inconvenienced by cough but be otherwise in good health. The work of Dr. Lilienthal showed skill in one of these most miserable conditions of the lung. In the picture which the speaker had presented he had amputated the lung; could not show the patient because he was dead, having died on the tenth day after the operation. The hilus was ligated en masse. It was a big mass of tissues but the ligatures gave way on the tenth day. Dr. Meyer had spoken of a case in which bismuth poisoning resulted. Dr. Beck had published in the *Journal of the American Medical Association* that a mixture of oil and bismuth was a very dangerous mixture, the

oil separating from the bismuth. Adding acacia to the oil produced solidification of the metal. He warned against substituting oil for vaseline. The bronchial openings in lung abscess could be closed by cauterization. He had shown last year a case in which seven bronchi had been opened and could be inspected ocularly. He had used an ordinary cautery, such as the rhinologists used when cauterizing the nasal mucous membrane, and had cauterized the mucous lining for about half an inch and in every instance the bronchus will close.

Dr. SYDNEY YANKAUER of New York considered the diagnosis of lung abscess by means of the roentgenogram subject to certain errors to which attention had been called by Major Dunham. In diseased lungs the abscess cavity distorted the lung itself, disturbed the findings, and made it difficult to recognize the location of the lung abscess by this method. Furthermore, the different lobes overlapped each other, the incisures between the lobes differed considerably even in the normal chest. Now there was one method of recognizing the location of a lung abscess which had not been mentioned here and of which the thoracic surgeons had not hitherto made sufficient use, namely, the endoscopic examination of the lung itself. The procedure of bronchoscopy was certainly well known, and universally practised, but its use in lung abscess cases was one to which he wished to call special attention. One could recognize with the bronchoscope whether the pus came from one side or both; and whether the pus came from one lobe or another by recognizing branches from which the pus was seen to exude. In bronchiectasis one could estimate the size of the bronchus; by evacuating the pus from the bronchiectatic cavity it remained clean, whereas in lung abscess, the pus continually reappeared from the bronchus leading to the affected lobe. It was an error to suppose, in doing bronchoscopy on a lung abscess, that one would see a pool of pus, a wide horizon, and an empty space above. When the bronchoscope entered a cavity which contained pus, the pus was immediately coughed out. The bronchiectatic cavity bore a close resemblance to a dilated bronchus. Of course, it was true that such diagnosis required experience and the bronchoscopist who had difficulty in entering the trachea with the bronchoscope would find a great deal more difficulty in recognizing the changes in the bronchial tree. A small number of these cases had come under his observation by means of the bronchoscope. These cases had been in the hands of internists, and had been refused operation by the surgeon, so that they were not particularly favorable cases. The treatment he had employed was irrigation of the bronchus by means of a return flow catheter whereby he was able to wash about a pint of solution through the affected lung. In about 15 cases in which he had been able to continue treatment for a sufficiently long time, three of them had been practically cured. When one considered that they were hopeless cases, and that 20 per cent. have been practically cured by pulmonary irrigation, the method was one that deserved to be continued. The most striking of these cases was a young girl referred to the speaker by Dr. Willy Meyer with well marked fluid level following tonsillectomy. The lung was irrigated twice a week, first with normal saline solution, later with a solution containing carbolic acid and iodine. In six months time the girl was cured and she had been well now for two years. The second case was a young man with bronchiectasis following pneumonia in childhood. At first he could turn the patient over at almost any hour of the day and evacuate foul smelling fluid. He had increased six inches in height, and was able to go back to his work. Those not cured had been freed of foul odor and were able to resume their occupation, coming to the hospital for irrigation once a week. He was sure that most of these cases would have been under the sod if not treated in this way.

Dr. HOWARD LILIENTHAL of New York said he could not have done any more to this man without killing him. The question of the collapse operations brought up the subject of the proper selection of cases for operation. He did not think that every lung abscess could be cured by operation. Probably not every bronchiectatic abscess needed to be operated upon. Dr. Yankauer was treating a case referred to him by the speaker by bronchoscopic lavage. The abscess was enormous and looked like an empyema, yet there had been so much improvement that it almost amounted to a cure. Cases in which there was a thin abscess wall might not require extirpation. In these cases there might be a chance for recovery by means of pneumothorax therapy. Ordinarily the gas collapsed the healthy part of the lung and not the abscess. But there was an extrapleural method of compression which, in the hands of Tuffier, had given good results, especially in apical disease. An incision was made in the second space down to the endothoracic fascia but not through the pleura. The pleura was pushed away, collapsing the abscess so that there was a large cavity which might be packed with gauze which was replaced from time to time until the extrapleural cavity gradually had filled with granulation tissue. The speaker's two first cases had died, the first of a general septic bronchitis (wrong diagnosis) and the second from the accidental opening of the pleura. In the third case he had had no trouble in pushing away the pleura and making a cavity to hold gauze the bulk of his fist. He had tried to make fat implantation, but the fat necrosed, not being from the same patient. He had finally used gauze and after three months thought he would take out the gauze and see if cicatricial changes had not taken place which would prevent the abscess from refilling. And indeed there was a lot of cicatrix around the abscess that held it down to a certain extent. The man, however, began spitting and coughing again and subjectively he was just about as bad as ever, though the cavity was much smaller. Then he had turned him over to Dr. Yankauer, and after a series of lavages he had become well enough to be about and do his work. The case was now pretty nearly cured. The cases that had to be operated upon were the progressive ones with indurated walls, with large abscess inside. Here nothing short of extirpation would suffice. But the death rate was high, probably not less than 60 per cent. These were cases for surgery because the patients would never get well by any other means, so far as his experience went.

Dr. CARL A. HEDBLOM of Rochester, Minn., said in the series of cases he had just reported there was one instance of complete spontaneous cure of pulmonary abscess following tonsillectomy, and one of spontaneous drainage through the chest wall. In the latter the patient had refused operation. He was still draining at the last report. He had tried pneumothorax therapy in two cases and it had been attempted elsewhere in two. One of his patients was cured, the other one had to be drained. One of the two treated elsewhere developed an extensive cellulitis of the chest wall. This patient had come to him with a large chronic abscess. He was one of the patients who finally died of hemorrhage. In his opinion expectant treatment in the hope of spontaneous cure was justifiable only for a few weeks and only in those cases that were progressively on the mend. Deferring operation in other cases seemed in some measure analogous to waiting for abscess to develop in case of appendicitis. The mortality was greatly increased by chronicity. Pneumothorax therapy seemed promising especially in acute centrally placed abscess that had perforated a bronchus. The method would always be limited in its applicability because of the frequency of adhesions preventing collapse of the lung.

Dr. WILLY MEYER agreed with Dr. Hedblom that there could not be drawn at the present time a proper border-line between lung abscess and bronchiectasis. He had once seen what he did not think possible before, a spontaneous cure of a lung abscess. In a case of lung abscess he had urged operation; but the patient and his family were not particularly inclined to follow this advice. While still in the ward, the patient slowly improved; later on he went home, where, according to report, he got entirely well without operation. In addition to the clinical examination for establishing the diagnosis, the steroscopic radiography and bronchoscopy were important. The latter should be done by one who would not do harm and who knew how to interpret correctly what he saw. With regard to aspiration, in former years he had never hesitated to push the needle into the lung when suspecting an

abscess, and had never seen harm. After the discussion of this question before the New York Society for Thoracic Surgery he had been doubtful, but the more he had seen since then, the more he had been inclined to aspirate *before* the time set for the operation. To stand before one's patient and not know exactly where and how deep to go in, and then to be obliged to find the pus with the patient on the operating table, was rather annoying. He believed this could be determined beforehand with safety in the great majority of cases. The treatment, as of any other surgical inflammation, was conservative and radical. The conservative treatment was what Dr. Yankauer had brought out, the method of bronchial irrigation as he had practised it. The girl to whom Dr. Yankauer had referred came from the Golden Gate and was almost dying on her way to New York. She had improved at the hospital here. He had called Dr. Yankauer to find out which lobe or lobes the pus was coming from, and had found all three lobes of the right lung affected. The girl was sixteen years old, and the parents did not want to take any chances. The girl was cured by irrigation. Concerning insufflation of nitrogen, one must differentiate between early and late cases.

Dr. TEWKSBURY of Washington had proved by his statistics that in early cases the establishment of an artificial pneumothorax was the operation of choice. Better still, of course, was prophylaxis, to avoid the occurrence of the disease. Since these cases had been discussed before many medical societies, specialists had taken great care in their tonsillectomies. They practised continuous aspiration of the blood with the help of the electric current. In late cases when the bronchial walls were harder and those of cavities often calcified, persistent collapse of the lung, even for several years, was frequently of no avail; as soon as the treatment was stopped the old trouble returned. He had had experience with all the conservative methods of operation. Following Professor Friedrich's advice, given the speaker ten years ago, he did not practise lobectomy in the majority of cases, and had come to the conclusion, that, with very few exceptions, the "*cure*" of advanced cases could be accomplished by lobectomy only, as Dr. Lilienthal's case here presented had again shown. However, one often could first tide over some of these patients with the help of a less severe operation, particularly those who had this offensive expectoration which made them outcasts from human society, so that they had to be isolated for months. By ventilating these cavities thoroughly, making a big hole in the chest wall and lung, and letting the air from outside pass through the cavities, often with the addition of pure oxygen insufflation, that odor disappeared, not to return again. The patient might retain a large pneumonic fistula, but that did not harm. One of his patients had such a large fistula, but was ready to get married. A few of these rather advanced cases could also be cured by incision of the lung and prolonged drainage. Much would depend, with reference to prognosis, upon *how long* the patient had been sick, before he came to operation. When presenting his patient with a persistent cavity; Dr. Lilienthal had said he did not know what it contained. The speaker would have put in a needle and determined whether it was air or fluid.

Dr. LILIENTHAL said it was air. He would not put in a needle.

Dr. MEYER, continuing, said he, too, was convinced it was air. In doing lobectomy experimentally in dogs, they had extirpated the lung at one sitting. There was usually primary union. Seventeen out of twenty-one dogs had recovered. Animals as well as human beings had by far too much lung. A few days later the dogs had jumped around at the Rockefeller Institute as if nothing had happened. Of course there had to be a cavity in the chest, and it was a question whether it was filled with air or with fluid. Just at that time a paper by Dr. Samuel Robinson had appeared from the Marburg Clinic, written in conjunction with Sauerbruch wherein it was stated that after lobectomy fluid was found in the chest. The speaker aspirated the dogs and found air, regularly. To prove how nature would get along with the artificial pneumothorax, Dr. Francis Carter Wood then very kindly and courteously had come to his help. At various intervals after the operation the dogs were bled to death by him under general anesthesia, formalin solution first having been injected into their vascular system, and the cadavers were frozen stiff. Then with a large saw transverse sections of the chest were made at various levels. It was seen that with advancing absorption of the air, the mediastinal contents gradually moved over to the costal pleura of the side operated on. But they would not adhere to that costal pleura. Nature formed a sort of new pleural cavity, the visceral portion being represented by the mediastinal tissues. In the case presented, and in similar ones, in which the organs and tissues could not move, the air enclosed, he believed, did not become absorbed. There remained a permanent pneumothorax filled with the nitrogen part of the air. The speaker believed that we were only at the threshold of this important and fascinating chapter. The point of greatest interest at the present moment was the finding of the correct indication, *how* to proceed in the given case, which patient should be treated with conservative operative methods, and which should submit to lobectomy. Certain it was, that a "cure" in advanced cases could be obtained only by means of lobectomy.

Dr. LILIENTHAL, in closing the discussion, said Dr. Brown had examined that man and he believed it was a pneumothorax. The title of his paper should have been "Lung Abscess, Multiple, Following Tonsillectomy, Report of a Case of Extirpation of the Right Lower, Middle and Part of the Upper Lobes, with Subsequent Atrophy Leaving No Lung in the Right Chest."

VII. Heart: The Aviator's Heart. Roentgen Ray Studies Under Conditions Simulating High Altitudes.—Dr. LEON T. LE WALD of New York presented these observations, which were made during the examination of U. S. Army aviators at the Medical Research Laboratory at Mineola, L. I. During the examination of aviators under reduced atmospheric pressure, in the low pressure chamber at this laboratory, Whitney (Medical Studies in Aviation, *Jour. Am. Med. Assoc.*, October 26, 1918) and his co-workers, had observed at pressures corresponding to altitudes of 18,000 to 20,000 feet an increase in the area of cardiac dullness in the case of certain aviators. Later a similar increase in the cardiac dullness was occasionally observed during the course of the low oxygen test conducted at the laboratory for the purpose of classifying aviators according to their ability to withstand the effects of high altitudes. The enlargement as observed by Whitney, was principally to the left, but occasionally right-sided enlargement was encountered in addition. Whitney ascribed the increased area of dullness in these cases to dilatation of the heart, and thought it was due partly to lowered tonus of the cardiac muscle because of the lowered oxygen content of the inspired air and of the blood and partly to fatigue such as occurred after excessive exertion, as in Marathon runners. The present studies had been undertaken to determine whether enlargement actually occurred under these circumstances, and if it did, what was its amount, whether its onset was sudden or gradual, what was its relation to the blood pressures and to the psycho-motor reactions of the aviator, and whether it was a conservative process designed to increase the output of blood by the heart or whether it was a true dilatation due to fatigue or exhaustion of the heart muscle. Two series of studies had been undertaken, one with the Henderson "rebreather," and the other in the low pressure chamber. The rebreathing experiments had been undertaken first because any changes observed would almost surely be due to diminished oxygen alone; whereas in the low pressure chamber they might be influenced by the change in pressure or by the expansion of abdominal gases, causing an upward displacement of the diaphragm. The Henderson rebreather consisted of an iron tank of at least 52 liters capacity provided with a water sealed spirometer and connected through tubing with a mouthpiece through which the subject breathed, the nose being clamped with a spring "clothes-pin." An arrangement of two mica check valves caused the inspired air to flow through one tube and the expired air through the other back into the tank. As the

experiment continued the supply of oxygen was reduced, which had the same physiological effect as rarefying the air in a low pressure chamber or ascending to a high altitude. In the first series, roentgenograms were made of aviators every five minutes while the subjects were on the rebreathing apparatus. The length of the run varied from 15 to 38 minutes. With the controls taken before and after the run there were thus obtained from six to thirteen roentgenograms of each heart. The greatest care was taken on the alignment of the tube, the patient and the plate, so as to make the roentgenograms properly comparable with one another, not only those of the same but also of different subjects. Teleroentgenegrams were made at a 2 meter distance, and were taken in both inspiration and expiration. Serial roentgenograms were made at 75 cm. in both expiration and inspiration, and in certain instances double exposures on one plate to show both inspiration and expiration. The exposures varied from 1/20 to 3/20 of a second at the 75 cm. distance and from 1/10 to 3/5 of a second at the 2 meter distance. Because of the shortness of the exposures it was thought necessary to time them for a definite period of the cardiac cycle in order to avoid variations in size due to systole and diastole. The timer was therefore actuated by a special mechanism set off by the pulse wave. By exactly superimposing a silhouette taken in expiration upon one of the same subjects taken in inspiration, the changes taking place in the shape and position of the heart could readily be seen—the excursion of the diaphragm upward in expiration and lowering of the apex of the thoracic cavity. Their results showed in many cases a decided broadening of the heart shadow to the right as well as to the left during expiration. The apparent broadening of the aortic arch, especially its displacement to the left, was very noticeable in such plates. This was perhaps best shown by making two exposures of a thorax on one plate, one during expiration and one during inspiration. They had divided the 86 men into three classes: (1) In 66 men no enlargement of the heart occurred under lowered oxygen pressure. The variations that occurred were so irregular they could not be attributed to oxygen want or to the progress of the test. (2) Nine men showed a more or less consistent increase in the transverse diameter toward the end of the test, with an average of 0.75 cm. increase. (3) In the remaining 11 there was a decrease in the transverse diameter.

Dr. WILLIAM H. STEWART of New York said cardiac dilatation at altitudes had been recognized for some time. He asked if Dr. Le Wald would tell just how reliable his mechanical devices were in recording on an *x*-ray plate or film the image of the heart at the same point in systole or diastole, and whether he took the combined images. Those familiar with fluroscopic examinations knew that there was considerable variation in the size of the heart during inspiration and expiration. It would seem difficult to obtain an image of the heart for comparative study at the same phase and at the same point in either inspiration or expiration. It would be interesting to know how Dr. Le Wald mastered these problems.

Dr. LE WALD, in closing the discussion, said they had given up trying to get the heart in systole, and after careful consideration of the whole subject had decided that with exposures of such length as they had they never did get systole. The point was very well taken, and personally he would like to be able to show a heart definitely taken in systole. He presumed from the technique that the hearts were all in diastole.

VIII. Posterior Mediastinum; Esophagus: 1. The Treatment of Cicatricial Stenosis of the Esophagus.—Dr. HENRY S. PLUMMER of Rochester, Minn., read this paper.

2. X-ray Findings wtih the Delineator in Cardiospasm.—Dr. MAX EINHORN, in conjunction with Dr. THOMAS SCHOLZ of New York, presented this paper. (See MEDICAL RECORD, November 1, 1919, xcvi, 18.)

3. Superior Esophagoplasty for Inoperable Cancer of the Lower Portion of the Esophagus and of the Cardia.—Dr. WILLY MEYER of New York said the greatest desire of all patients suffering from stricture of the esophagus naturally was to regain the power of swallowing. In operable cases this could be accomplished if the patient survived; but not in inoperable malignant complete stricture of the esophagus and cardia, unless nature favored these unfortunates by an ulcerative process with breaking down of the tumor, and consequent reopening of the tube, or radium treatment produced a superficial slough. In patients with malignant stricture, too far advanced to allow radical operation, the end could be attained only by the procedure outlined. In order to do for these patients what the present status of thoracic surgery offered, it was proposed, after determining the inoperability of a cancer of the esophagus by means of a thoracotomy, to divide the esophagus above the tumor, invert the distal portion and bring out the proximal stump through the external esophagotomy wound at the neck and place it subcutaneously, as was done nowadays in the typical radical operation for an operable malignant growth of the esophagus. The same procedure was advocated in patients in whom on gastrostomy for cardiac malignancy far reaching glandular involvement was found in the lesser omentum, making an ultimate cure by operation extremely doubtful. He considered this interference indicated particularly from a humane point of view and placed it on the same level as gastroenterostomy for an inoperable carcinoma of the pylorus. A patient thus operated upon was shown in lantern slides. Although greatly reduced in weight (88 pounds) she stood the operation as such very nicely, air-tight thoracic drainage being made use of for after treatment. Through a rubber tube, connecting the lower end of the transposed proximal stump with the gastrostomy fistula the patient could swallow nicely. On the fourth day after the operation symptoms of pneumonia developed, to which she succumbed on the thirteenth day after operation, retaining up to the end perfect power of swallowing.

Major LEON T. LE WALD of New York said Dr. Plummer's record of six cases occurring in pregnancy reminded him of a case of pyelitis with cortical abscesses in the kidney. In the lower third of the esophagus there was an ulceration process which was either metastatic or came on at the same time as lesions in the kidney. That fitted in very well with his observation.

Dr. MAX EINHORN of New York was very much interested in Dr. Plummer's paper and congratulated him upon his results. He had often used a thread with a tiny olive at the end and thought it went better. He had had a patient who had by mistake swallowed some poison, caustic soda, if he remembered correctly, and had come to the hospital vomiting blood. A duodenal tube was introduced and the patient was fed and for two weeks kept in good condition, but after a while it was necessary to dilate the stricture. He got along pretty well. With another patient, sent by Dr. Dickinson, they had had no trouble in stretching the benign strictured esophagus, Dr. Willy Meyer having previously established a gastric fistula.

Dr. NATHAN W. GREEN of New York, had been very much interested in Dr. Plummer's presentation of this rather avoided subject. He had had a few cases, not anywhere near the series Dr. Plummer had mentioned. He had had a few by himself and two in conjunction with Dr. Abbe. In one he was able to pass a filiform by the aid of an esophagoscope, which was impossible to do in any other way. That was the case of a little girl who came from Massachusetts. In another case, a little boy, from the South, the same thing was done, and in both these cases Dr. Abbe did his string sawing operation. Two others were also treated by dilatation by direct vision with the aid of the esophagoscope, without Dr. Plummer's sound, but putting an ordinary sound down through the esophagoscope and gradually stretching the stricture. He used his own esophagoscope made by Wappler. One patient, operated on by Dr. Abbe's method several years ago, went along well for a while, but did not come back regularly for bougies and four or five years ago she was sent to him. He dilated her through the esophagoscope at first and later with a larger bougie than could be so used, but could not get sufficient dilatation until he did another string sawing operation after another gastrostomy. He went right alongside of the old gastrostomy and found it firmly adherent to the anterior ab-

dominal wall. That patient returned to him now for bougies about every four to six weeks. Another patient swallowed sulphuric acid, thinking it was whiskey. He did a string-sawing operation on him. The cicatricial tissue did not go through such a long wait before he came to me and for that reason the stricture stayed open for as much as two months. It was a year or so since he had dilated. These cases were very satisfactory.

Dr. MEYER asked Dr. Plummer whether he started his operation with a gastrostomy.

Dr. PLUMMER replied that he had never made a gastrostomy, except under two conditions: provided at the time the patient came with inanition, a chance that he did not dare to take; second, patients whom he must send home and of whom he thought the local doctor could not take proper care.

Dr. MEYER had always taken a great deal of pleasure in treating this class of cases. It was of the keenest interest to him to see how well patients, even young ones, could stand the Abbe string method. That big silk string being pulled to and fro never did any harm, and right afterward the sounds could be introduced. He agreed with Dr. Green that if such cases came under his care he would do as Dr. Plummer had suggested. This procedure certainly greatly simplified the whole plan of treatment.

Dr. GREEN asked Dr. Plummer if he was familiar with Gossett's article written earlier than 1906, in which he did an open thoracotomy on two of these cases and passed a bougie from the mouth down. As he remembered it Gossett had said that the whole stenosis was due to periesophageal adhesions rather than to cicatricial tissue in the esophagus itself. That had made an impression on him, but he had never followed out this procedure.

Dr. PLUMMER said a patient could not be induced to swallow a braided silk; it must be a twisted silk. It must be the finest obtainable. A sound must be passed and then the contracture stretched. He had never seen a case of cicatricial stenosis that he did not have eating beefsteak within six weeks.

Dr. LILIENTHAL had dilated to the size of his little finger and feared it would cause ulceration if solid food were taken. He was interested to know from Dr. Plummer that this fear was unfounded.

Dr. PLUMMER had seen three or four hundred cases, and had never encountered one in which there were either fissures or ulcers. He allowed the patients beef steak when he thought them in condition for it. In case meat got stuck in the esophagus he pulled it out with the esophagoscope. In the hands of a trained man the dangers were relatively little.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PRACTICAL DIETETICS By ALIDA FRANCES PATTEE. 543 pages. Published by A. F. Pattee, Mt. Vernon, N. Y.

MANUAL OF PSYCHIATRY. Fifth Edition. By A. J. ROSANOFF. 684 pages, with illustrations. Published by John Wiley & Sons, Inc., New York.

THE SURGICAL CLINICS OF CHICAGO. Vol. 4, No. 2. 222 pages, with 60 illustrations. Published by W. B. Saunders Company, Philadelphia, Pa.

DIATETIK DER MAGER- UND DARMKRANKHEITEN. By Prof. Dr. I. BOAS. 216 pages. Published by George Thieme, Leipzig.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Edited by SIMON FLEXNER, M.D. 609 pages, with illustrations. Published by the Rockefeller Institute for Medical Research, New York.

TRANSACTIONS OF THE AMERICAN ASSOCIATION OF GENITOURINARY SURGEONS, Volume XII. 415 pages, with illustrations. Published by Williams & Wilkins Company, Baltimore.

Miscellany.

Artificial Eyes in Antiquity.—Ebers, the celebrated Egyptologist, said that a mummy with an artificial eye had never come to light and that the papyrus Ebers made no mention of such objects. However, the guidebook of Elliot Smith to the collection of mummies in the Cairo Museum speaks of mummies with false eyes, although no details are given. In the *Musée du Cinquantenaire* at Brussels are eyes of marble, terra cotta, enamel, glass, etc., such eyes being called "mummies' eyes." These eyes are found in masks of mummies so-called and are made of marble with glass inserts to represent the cornea. This is the most familiar construction, but there is much detail in the workmanship in which other materials are used. In some there is a sort of mounting in bronze. An eye of a later cultural period is constructed of terra cotta and enamel. The latter is dead white and serves to denote the sclerotic while the part which corresponds to the cornea and iris is greyish blue. The margin which roughly imitates the palpebral border is also of terra cotta. The Egyptian excelled in this kind of work, but while such eyes were suitable for effigies of all kinds there is no evidence adduced to show that they were ever worn during life. Idols and statues of rulers, etc., were alike provided with eyes which were often of superior workmanship containing precious stones. The first mention of a prosthetic artifical eye worn by a living subject is by Paul of Egina, seventh century after Christ, unless a mention in the Talmud is authentic, in which case the period would be moved back to somewhere between the second and fifth centuries of our era. Professor Hirschberg, the distinguished Jewish ophthalmologist, however, does not uphold the correctness of the interpretation that a true prosthetic eye is meant in this Talmudic passage.—Professor Van Duyse in *Archives Médicales Belges*, September 1919, lxxii, 9.

Hydatid Disease in Uruguay.—According to reference works Iceland and Australia are the two countries or areas of the world most scourged by the dog tape worm, but according to Zerbino, Uruguay cannot be very far behind them. Cranwell has shown the extent of the scourge in Argentina, as well, and the disease exists throughout the entire South American continent. In Uruguay the child is attacked and the youth as a result are decimated. During the five-year period, 1913-1917 inclusive, the personal statistics of Zerbino cover respectively 105, 139, 165, 157, and 152 cases, and from a fourth to a third were under the age of 15. In the same years in one of the Uruguay hospitals 718 cases were treated, of which 216 were in children. Apparently the disease is increasing in frequency, but this alleged increase is probably only improved diagnosis. The most frequent location is the liver, with 60 per cent., after which comes the lung with 21 per cent. Multiple location is especially common in childhood. Uruguay must soon take up this problem seriously, for it is a veritable national plague.—*La Presse Médicale.*

Alcoholism in Spain.—The director of an insane asylum in the province of Gerona sent a question-

naire to all the physicians of the province in order to make a survey of alcoholism. Not more than a quarter of the number made replies so that a complete survey is out of the question. Data were obtained from 59 communities out of 247, from whence it appeared that there was alcoholism in 47 and no alcoholism in 12. In 10 of the 47 it was present in marked degree. Intoxication was common in 34 places and the principal drinks were wine and aguardiente. Most of the alcohol was drunk in taverns, next came the home, then the restaurant, and finally some men drank while at their work, presumably wine, taken along with them. Since most men in the province are laborers this is the occupation most frequently mentioned. The work done by drinkers was mostly hard labor with exposure. Factory workers apparently do not indulge immoderately.

Replies concerning the nature of the morbidity set up by chronic alcoholism seem vague and there is no mention of control figures. The number of cases of alcoholism in women and children is not alarming, it being quite exceptional (9 children and 44 women in a large population). Replies do not show that alcohol has caused alienation in the descendants of drinkers. The abuse of alcohol is ascribed to three factors acting on a morbid predisposition—imitation, belief that alcohol invigorates, and defective nourishment of men exposed to hard labor.—*Revista Espnañola de Medicina y Cirugia.*

Bahia Graduation Thesis for 1919.—In South America the graduation thesis is still an important feature of undergraduate life and the Bahia correspondent of the *Brazil-Medico* in the issue of March 13, 1920, xxxiv, 11, selects four of these as of special merit. The first deals with the intravenous injection of sodium iodine in nervous maladies. The author is Barretto de Almeida. The technique used is the modification of Klemperer's original method by Professor Pinto de Carvalho. Twenty case histories are given which illustrate the advantages of the resource, but the reviewer omits details. The second thesis is by Peixotto de Magalhaes Netto and is devoted to the etiopathogeny of the Morel-Kraepelin disease, by which term the author indicates dementia precox. The author accepts the views of Professor Austregesilo of Buenos Ayres in which autointoxication of endocrinic motivation is regarded as the chief casual factor. The third contribution is by Guerra and is devoted to the early Röntgen diagnosis of pulmonary tuberculosis in which the technique and personal observations are alike well represented. The remaining thesis by da Silva deals with infantile scorbutus, a field in which South America has been well represented in literature by Figueira of Rio, Gesteira of Bahia, and Werneck, who studied the malady in Santos. The correspondent does not refer to any section dealing with the symptomatology. In treating of the cause of infantile scurvy the author of the thesis holds, in agreement with many authorities, that this is multiple and that various single factors and nexuses may give rise to a common syndrome.

Historical Notes on the Enema.—While certain primitive peoples practised an equivalent to the civilized clyster, others showed a horror of it when the first European visitors sought to employ it for medical purposes. The subject is outlined by Albinana in *El Siglo Médico* for March 27, 1920, lxvii, 3459. The occasion was furnished by a recent statement that the rectal syringe is an apparatus foreign to Spanish culture and was a shameful and proscribed article of furniture in old Madrid. Sprengel notes the horror shown towards it by the "Indians," while on the contrary certain primitive African mothers squirted water into the infant rectum by means of a bamboo pipe. In Nigricia a certain kind of calabash naturally adapted for the purpose has been described and photographed by Kermogaut. Both the apparatus and technique of use seem fairly complex. The ordinary syringe used in antiquity and the Middle Ages seems too simple in design to have been the invention of any one man, but various medical men have received the credit for it. Thus, according to some, no description of a syringe is found prior to the works of Albucasis. Late in the XV century one Gatenaria, an Italian physician, seems to have at least invented an improved model.

The first illustration of a syringe is found in a work published by Brundiswig (?) in 1497 at Strassburg. The ancient use of the clyster was a function of the apothecary who appears to have been empowered by custom or law to give injections when it was deemed necessary. In 1329, for example, a French apothecary is known to have charged a fee of 32 sous for giving an enema to a lady. Apparently he was a profiteer of those days, for there is other evidence to show that the regular fee was 10 or 12 sous. The rectal use of the syringes said to have been discovered among the relics of ancient peoples, as the Etruscans, is naturally more or less speculative.

The First Bordeaux Medical College.—As early as 1411 there was a so-called College of Physicians in Bordeaux which functioned only as an examining board for candidates in medicine. In 1441 Pope Eugene IV founded the University of Bordeaux. In the original college the candidate must have practised for two years in the jurisdiction of the Parliament of Bordeaux and must have been a Catholic and of good moral character. During the two years which followed his going before the board he was to pass six examinations, two of which were to be held in the City Hall in the presence of the justice of the peace, a jury and the public. The candidate was required to present a thesis which should especially demonstrate his general culture outside of medical subjects. The first faculty to examine candidates in this manner was originally limited, at least for a time, to a single examiner who was frequently a Spaniard or converted Jew. When the University was formed the study courses comprised theology, law, medicine and the "arts." In 1573 the medical college was required by law to have at least four teachers. In 1414 a German medical man named Ram was authorized to practice by the examining board and a letter is preserved in the municipal archives from which it appears that in 1414 the medical practitioners of Bordeaux had for some reason which the writer of the letter does not state become extinct for the time being.—*El Siglo Médico.*

INDEX.

A

Abdomen, gas cysts, of the, 203; the acute, 423.
Abdominal aortitis, 148; drainage, 248; emergencies, 750; incisions, 581; tumors, the diagnosis of, 138.
Abnormalities, gastrointestinal, a few roentgenograms demonstrating, 84.
Abortion, etiological factors in, 1013.
Abrams, Albert: electrotonic reactions of Abrams, overt phenomena, 565; the physics of percussion, 958; Abscess, cerebellar, report of two cases of, 499; deep cervical and thrombosis of the internal jugular, 502; dysenteric, of the liver cured by emetine without operation, 117; lung, 1096; post-tonsillectomy, resection of the lung for, 1096; pulmonary, bronchioscopic treatment of bronchiectasis and, 216; pulmonary, bronchoscopic treatment of bronchiectasis and, 251; of the frontal lobe, simulating frontal sinusitis, 500; of the lung, 807.
Acanthosis nigricans, acute benign cases of, 706.
Acetonuria of fatigue, 571.
Acidosis and diabetes, the relation of glycogen to, 403; in nephritis, 497.
Acne vulgaris, treatment of, 88.
Acrocephaly with deformities of the extremities, 84.
Acrodynia, 849.
Actinomycosis, acute cervicofacial cancer simulating, 1013; extensive, in a soldier, recovery, 167.
Addicts, the after care of, 1050.
Adenomata, mild types of thyroid toxic, 633.
Adrenalin and quinine, antagonism of, 313; injection of, in the diagnosis of latent diseases, 370.
Adult life, preventable diseases of, 626.
Aged, artificial impaction of the femur in the, 247.
Air swallowing, hypochlorhydria and, a clinical lecture on, 118.
Alcohol, how to remove the craving for, 885; in the cerebrospinal fluid, 940; methyl, blindness after ingestion of, 1092; methyl, poisoning by, report of cases, 764; the effect of on the duration of life, 839
Alcoholism in Spain, 1100.
Alimentary poisons, 1054.
Alimentation in children, 158.
Aliments, 664.
Alveolitis, influenza as a pulmonary necrotic, involving the endocrines, 926.
Amenorrhea, complete, rapidly growing multilocular ovarian cyst associated with, 294.
American Legion, Caduceus Post of the, 657.
Amyl nitrite in the peripheral vasoconstriction of the shocked subject, 835.
Anaphylaxis, alimentary, from pancreatic insufficiency, 657; antipyrine, 625; epilepsy and, 159; migraine and, 72.
Anastomosis, uretero-ureteral, 337.
Anemia, alimentary, 201.
Anemias, toxic, 201.
Anesthesia, ether-oil colonic, 938; general, a mixture of ethyl chloride, chloroform, and ether for; an experience in war surgery, 247; general, the present status of, from the hospital viewpoint, 651; in cerebral and spinal surgery, 231; in obstetrics, 624; local, advantages of, in thyroid operations, 932; local, in infancy and childhood, 856; local, in the radical cure of hernia, 274; problem, the, in lung surgery, 987; Research Society formed, 240.
Anesthetics in obstetrics with special reference to nitrous oxide, 356.
Aneurysm, jugulocarotid, 623; of the ascending arch of the aorta in a boy of thirteen years, 83; of the thoracic aorta, frozen sections from two cases of, 809.
Angina, Vincent's, fatal, 592; Vincent's, simulating chancre of the tonsil, 963; Vincent's, specific treatment of, 159.
Angioma of the stomach, 220.
Angiomata, senile, the pathology of, 1047.
Anilin poisoning, chronic, 401.
Animal organism, motility in the, 47.
Anomalies, anatomical, the clinical importance of, in biliary surgery, 1052.
Anomaly, a congenital, of the duodenum, and its surgical significance, 248.
Anorectal operations, technique of, under local anesthesia and rectal instrumentation, 580.
Anosmia and epilepsy, 1008.
Anthrax as an accident, 917; comparison of surgical and nonsurgical methods of treatment, 969.
Antipyrine anaphylaxis, 625.
Antituberculosis movement, the, in the United States prior to and since the formation of the National Tuberculosis Association, with brief tributes to its departed leaders, 1071.
Antrum, treatment of malignant tumors of, 884.
Anxious states, arterial pressure in, 332.
Aorta, aneurysm of the ascending arch of the, in a boy of thirteen years, 83; rupture of the, 466; rupture of, from vomiting an accidental "violence to the physical structure of the body," 1002.
Aortitis, abdominal, 148.
Appendicitis, acute, the management of, in the later weeks of pregnancy, 892; caused by ameba dysinteriæ, postoperative perforation of an amebic ulcer of the cecum, 894; chronic, 1082; chronic, bad results following operations for, 372; chronic in children, 801; chronic, remarks on the diagnosis of right iliac fossa pains and the end results of 200 operations for, 579; etiology of, 30; gangrenous, co-incident with labor, 166; the relation of, to intrapelvic disease in women, 1052; without protective stiffening of the abdominal wall, 751.
Appetite, defective, in children, hyperchlorhydria—a frequent cause of, 786.
Apoplexy, prophylactic vaccination against, 172.
Arches, rebuilding broken, 519.
Arrhythmia, a case showing apparent paradoxical respiratory, 969; complete, the interpretation of experimental and clinical data of, 1044; complete, the prognosis of, 323.
Arsenical poisoning, delayed, 842.
Arsphenamine reactions, 842; the administration of, by retention enema, 144.
Arterial pressure in anxious states, 332.
Arteriosclerosis, dyspnea and early death in, 279.
Arthritis, chronic, with subcutaneous nodules and enlargement of lymph tubes and spleen, 161; surgical and non-surgical treatment of the prostate and seminal vesicles in, 587; tuberculous, 712.
Ascariasis, the dangers of, 541.
Ascaris lumbricoides, the dangers of infestation with, 655.
Asthma, a new conception of, 156; bronchial, some personal views of, 611; results of the peptone treatment of, 928; treatment of bronchial, 88.
Astragalus, fracture of the posterior tubercle of the, vs. inconstant os trigonum, 1011.
Atelectasis, congenital disseminated, with x-ray findings, 83.
Atropine in general diagnosis, 332.
Atrophy, infantile spinal progressive muscular (Werdnig-Hoffmann), 851.
Aulde, John: calcium therapy, 493; mineral salts for disordered heart action, 1007; applied calcium therapy: a study of deficiency diseases, 257; the diet and health; amount and kind of food required, 947.
Autointoxication, ovarian, 203.
Autoserum therapy (intra-spinal) in encephalitis, 1079.
Aviation candidates, the incidence of nose, throat and ear diseases among, 842.

B

Bacteriemia, a case of, treated by blood transfusion, 713.
Bacteriotherapy, treatment of some chronic processes by, 489.
Bahia, graduation thesis for 1919, 1101.
Bainbridge, William Seaman: A study of certain bands in the right upper abdominal quadrant. Illustrated by cases, 593.
Bandler, Samuel Wyllis: The balance between the endocrines and in each individual endocrine, 638; the instincts, the emotions, and the endocrines in sterility, 383.
Bands, a study of certain, in the right upper abdominal quadrant. Illustrated by cases, 593.
Barbarism, the return to, 107.
Bartholomew, R. A.: the prevention of

peritonitis in a case of intrapartum infection subjected to extraperitoneal cesarean section, 1080.
Basal metabolic rate estimations, the clinical interpretation of, 803; metabolism determinations in general internal diagnosis, 663.
Basedow's disease, diagnosis of, 664; early, 424.
Bassler, Anthony: The diagnosis of chronic gall-bladder pathologies, 889.
Bateson, J. C.: The philosophy of human sympathy, 787.
Bath, carbonated brine, the physiology of the, 1090.
Beard, questions as to shaving or wearing a, 703.
Beerwort, can one prepare an alkaline? 963.
Begging, suppression of, in Madrid, 79.
Bell, Robert: The cancer enigma, 346.
Beriberi among the Chinese in France, 332; as a mask for other affections, 492; scurvy and, the treatment and mangement of disease due to deficiency of diet, 331.
Berkeley, William N.: Comments on the function and clinical uses of the pineal gland, 12; preliminary report on a new method for the clinical diagnosis of toxic thyroid states. With a note on the serological technique, by John Koopman, 1035.
Bernhard, Adolph: Summary of the chemical blood findings in thromboangiitis obliterans, 430.
Bile, enemata of, in constipation, 1047.
Bills, three bad, 491.
Birth rate, falling, in Great Britain, 242.
Bismuth subnitrate, acute poisoning from, 802.
Bitters, 424.
Bladder, diverticula of, 236.
Blindness, after ingestion of methyl alcohol, 1092; wood alcohol, lumbar puncture in, 664.
Blodgett, Stephen H.: Saccharin, 521.
Bloedorn, W. A.: The barbarous custom of smoking, 185.
Blood counts in diagnosis and treatment, 348; examinations, mistakes and puzzles in, 289; Blood, human, variability in the non-protein nitrogenous constituents of, 1045; injections, intramuscular, as nutritional aids, 856; pressure, high, passive hepatic congestion associated with, 792; pressure in operative surgery, 411; serum, the variations of residual nitrogen in the, 148; the coagulation time of the, in the newborn with special reference to cerebral hemorrhage, 854; transfusion, see *Transfusion;* vessels, heart and, the effect of arteriovenous fistula upon the, 801.
Boarding out, advantages of over institutional care, 714; problems of, with an attempted solution, 677, 714; department of the New York Nursery and Child's Hospital, 714.
Body, the relationship of the external appearance of the, to disease, 632.
Boeckel, Professor, and Strassbourg University, 1024.
Bone grafting, autogenous, for repair in fractures of long bones, 339.
Bone-setter, medical degree proposed for a, 199.
Botulism, an outbreak of, 157; mild, with multiple eye symptoms, 534; preliminary report of a study of the antitoxin of bacillus botulinus, 540.

BOOK REVIEWS:

American illustrated dictionary, by W. A. Newman Dorland, 456.
Amœba, the, living in man. A zoological monograph, by Clifford Dobell, 1055.
Anaphylaxis and anti-anaphylaxis and their experimental foundations, by A. Besredka, 929.
Anatomy, principles of, as seen in the hand, by F. W. Jones, 1093.
Anesthésie à la stovaine en chirurgie et en médicine veterinaire, anesthésie régionale, anésthesie locale, by Gustave Peral, 665.
Anhasia and associated speech problems, by Michael Osnato, 1093.
Bakteriologie, die experimentelle, und die Infektionskrankheiten mit besonder Berücksichtigung der Immunetätslehre, by W. Kolle and H. Hetsch, 929.
Bakteriologie, praktische, von L. Paneth, 929.
Cancer, the medical treatment of, by L. Duncan Bulkley, 31.
Charaka Club, the proceedings of, 371.
Chemistry, a laboratory manual of physiological, ninth edition, by Elbert E. Rockwood, 886.
Dental caries and oral sepsis, the prevention of, by H. P. Pickerill, 333.
Dental extraction, an atlas, with notes on the causes and relief of dental pain, by C. Edward Wallis, 80.
Diatermia como medio de tratamiento de los processos ulcerativos de aparato digestivo, by Santiago Carro, 665.
Einige Erfahrungen über die Therapeutische und Diagnostische bedeutung der Milchinjecktionen besonders in der Ophthalmologie, by von Gerda Uddgren, 707.
Errors of accommodation and refraction of the eye and their treatment, by Ernest Clarke, 371.
Exact diagnosis, the, of latent cancer, an inquiry in the true significance of the morphological changes in the blood, by O. C. Gruner, 333.
Examens de laboratoire du médicin practicien, by Guy Laroche, 456.
Fatigue, la, de l'appareil visuel chez les ouvriers mineurs, by M. Stassen, 929.
Fatigue study, the elimination of humanity's greatest unnecessary waste, a first step in motion study, by Frank B. and Lillian M. Gilbreath, 414.
Ferite del retto, by E. Ricciolli, 752.
Foot care and shoe fitting, a manual of. For officers of the U. S. Navy and U. S. Marine Corps, by W. L. Mann and S. A. Folsom, 752.
Genito-urinary surgery, an outline of, by George Gilbert Smith, 160.
Half a century of smallpox and vaccination, by John C. McVail, 333.
Ido: Exhaustive text-book of the international language of the delegation and fundamentals of an artificial language, by Max Talmey, 31.
Industrial medicine and surgery, by Harry E. Mock.
Long, Dr. Crawford W., the distinguished physician-pharmacist, by Jos. Jacobs, 707.
Lumbalpunktion, die. Technik der Lumbalpunktion. Allgemeine und spezielle Diagnostik des Liquor cerebrospinalis. Therapeutische Anwendung der Lumbalpunktion, by Karl Eskuchen, 929.
Manual of obstetrics, by Edward P. Davis, 414.
Medical Clinics of North America, November, 1919. Mayo Clinic Number. Vol. 3, No. 3, 886.
Medical Clinics of North America. January, 1920. Boston Number. Vol. 3, No. 4, 886.
Medical Clinics of North America. Vol. 3, No. 2, September, 1919, 414.
Medicine, a concise history of, by Sir William Osler, 752.
Méningite tuberculeuse de l'enfant, by A. Lesage, 333.
Mind and its disorders, by W. H. B. Stoddart, 707.
Mustard gas poisoning, the medical aspects of, by Alfred Scott Warthin and Carl Vernon Weller, 752.
Narcotic Problem, the, by Ernest S. Bishop, 371.
Nervous and mental diseases, by Archibald Church and Frederick Peterson, 752.
Nose, paranasal sinuses, nasolacrimal passageways, and olfactory organ in man. A genetic, developmental, and anatomico-physiological consideration, by J. Parsons Schaeffer, 707.
Nutrition, the, of the fetus, by J. Morris Siemons, 333.
Obstetrics, a manual of, by John Cooke Hirst, 752.
On facial neuralgia and its treatment, with especial reference to the fifth nerve and the gasserian ganglion, by J. Hutchinson, 707.
On gunshot injuries to the blood-vessels. Founded on experiences gained in France during the Great War, 1914-1918, by George Henry Makins, 1055.
Opium monopoly, the, by Ellen N. La Motte, 752.
Our nervous friends. Illustrating the mastery of nervousness, by Robert S. Carroll, 31.
Outlines of organotherapy, by Henry R. Harrower, 371.
Oxford medicine, advance pages, edited by Henry A. Christian and Sir James Mackenzie, 333.
Pasteur—the history of a mind, by Emile Duclaut, translated and edited by Erwin F. Smith and Florence Hedges, 886.
Pathogenic bacteria and protozoa, a text-book upon the, ninth edition, by Joseph McFarland, 886.
Pathologie digestive, leçons de, par M. Loeper, 767.
Peritoneum, the, by Arthur E. Hertzler, 665.
Physical diagnosis, principles and practices of, fourth edition, by John C. DaCosta, Jr., 1055.
Physiology, a text-book of, by Martin Flack, 31.
Physiology, an introduction to general, with practical exercises, by W. M. Bayliss, 886.
Physiology, human, a text-book of. Including a section on physiologic apparatus. Sixth edition, by Albert P. Brubaker, 929.
Praktikum der medizinischen chemie einschliesslich der forensischen Nachweisl für Medizines und Chemiker, by Sigmund Fränkel, 1055.
Progressive Medicine, edited by H. H. Hare, assisted by Leighton F. Appleman, December 1, 1919, 371.
Psychiatric-Neurologic examination methods with special reference to the significance of signs and symptoms, by August Wimmer, translated by Andrea W. Hoisholt, 31.
Psychoses of the war, including neurasthenia and shell shock, 160.
Quarterly Medical Clinics, Vol. 1, No. 2, January-April, 1919, by Frank Smithies, 31.
Refraction of the eye, by Gustavus Hartridge, 371.
Sanitation for public health nurses, by Herbert Winslow Hill, 414.
Shell-shock and other neuropathic problems presented in five hundred and eighty-nine case histories from war literature, 1914-1918, by E. E. Southard, with a bibliography, by Norman Fenton 414.
Skin, common diseases of the, with notes on diagnosis and treatment, by G. Gordon Campbell, 886.
Sterility in women, by Arthur E. Giles, 160.
Surgery, the students text-book of, by H. Norman Barnett, 456.
Surgical Clinics of Chicago, Vol. 3, No. 3, June, 1919, 665.
Surgical Clinics of Chicago, Vol. 3, No. 4, August, 1919, 929.
Surgical Clinics of Chicago, Vol. 3, No. 5, October, 1919, 929.
Tension artérielle en clinique; sa mesue, sa valeur séméiologique, by L. Gallavasdin, 665.
Terminologie, medizinische, von Walter Guttmann, 1093.
The soul in suffering, a practical application of spiritual truths, by Robert S. Carroll, 31.
Transactions of the fortieth annual meeting of the American Laryngological Association, 160.
Tuberkulösen Infektion, Behandlung der, mittels antitoxischer Heilkörper, von Emanuel Wein, 1093.
Urethroscope, the, in the diagnosis and treatment of urethritis, by Major N. P. L. Lumb, 333.
Urology, a text-book of, in men, women and children; including urinary and sexual infections, urethroscopy and cystoscopy, by Victor Cox Pedersen, 80.
Vicious circles in disease, by Jamieson B. Hurry, 371.
War Neuroses and shell shock, by Frederick W. Mott, with a preface by the Rt. Hon. Christopher Addison, M. P., 80.
Women, diseases of, by Charles M. Green, 1093.
X-ray plates and films the systematic development of, by Lehmann Wendell, 752.
Year-book of Pharmacy, 1055.
Brachial birth palsy, a pseudo-paralysis of shoulder-joint origin, 123.
Brain, gunshot wounds of, with retained missiles, 334; lesions in gas poisoning, 766; tumor statistics, 417.
"Brazil Medico," changes in the appearance of, 654.
Breast, male, the prognosis of cancer of the, 961; malignant and benign tumors of the, 249.
Brill, A. A.: The empathic index and personality, 132.

Brill, 1. C.: Autoserum therapy (intraspinal) in incephalitis lethargica, 1079.
Brine bath, carbonated, the physiology of the, 1090.
Brodsky, Emanuel: some points of genesis and diagnosis of mental diseases, 94.
Bronchi, the physical signs of foreign bodies in the, 541.
Bronchial function, roentgen ray studies of, 251.
Bronchiectasis and pulmonary abscess, bronchoscopic treatment of, 216; and pulmonary abscess, bronchoscopic treatment of, 251; lecture on, 970.
Broun, Leroy: polycystic kidney of a typical character, 735; the gynecological patient of the general practioner, 635.
Bryce, C. A.: returning to sensible therapeutics, 881.
Buerger, Leo: the pathology of thromboangiitis obliterans, 431.
Bulkley, L. Duncan, and L. Bulkley Cady: Cancer death rate in New York City during 1919, 486; on the cure of cancer, 941.
Burdett, Sir Henry, death of, 1010.
Burnham, A. C.: community health units and health insurance, 103.
Burns, electrical, 237; facial, plastic operations for, 504; treatment of, since the close of the war, 751.
Burrows, Elliott C.: intestinal toxemia —its medical and surgical treatment, 398.
Burrows, Waters F., and Burrows, Elliott C.: Influenza. A confirmatory report upon the abortive action of quinine dihydrochloride, 235.
Butter fat and the child's weight, 256.

C

Cacodylate of soda in paralysis agitans, 615.
Cadbury, William W.: the pandemic of influenza as it affected Canton, China, 391.
Caduceus Post of the American Legion, 657.
Calcium salts, would the intraspinal injection of a solution of "cause instant heart-block?" 403; therapy, 493; therapy, applied, a study of deficiency diseases, 257.
Calculi in the salivary ducts, 970.
Calories, do, measure the value of food, 78, 86.
Camphor, 814.
Cancer, acute cervico facial, simulating actinomycosis, 1013; death rate in New York City during 1919, 486; enigma, the, 346; in animals, 840; inoperable, superior esophagoplasty for, of the lower portion of the esophagus and of the cardia, 1098; involving the mouth, 249; magnesium in, 751; mammary, statistics of, 706; on the cure of, 941; of the large intestine, surgery of, 937; of the male breast, the prognosis of, 961; of the rectum, 370; of the tongue, treatment of inoperable, 158; of the uterus, late results in the radium treatment of, 202; of the uterus, radiotherapeutic and other methods of treatment of, 603; of the uterus, radium therapy of, 369; of the uterus, the value of cystoscopy in, 1044; possible contagion of, 578; its problem, the, 570; probiem, the, a contribution toward its solution, 444; radium and, 198; research, 799; statistics, improvement in, 238; the control of an appeal to the practitioner, 732; the relation of, to the prolongation of human life, 415;
Cardiospasm, x-ray findings with the delineator, 1098.
Canities, sudden, a note on cases of, in history, 609.
Caput coli, dilatation and plication of the, 218.
Carbohydrates, the rôle of, in the treatment of toxemias of early pregnancy, 577.
Carbuncle, an efficient treatment for, 339.
Carcinoma of the rectum, operation for, 937; of the vulva. No recurrence for three years, 206; report of a case of bilocular uterus with, in the left horn, 604; squamous cell, of the kidney, 935.
Cardiac affections, see also *Heart Disease.*
Cardiological topics, on some present-day, 305.
Cardiospasm, impermeable, on retrograde stretching in the treatment of, 983; X-ray findings with the delineator on, 1099.
Cardiotherapy, intracardiac pressure as a standard in, 970.
Cardiovascular diseases, psychopathies and neuropathies of, 704; stimulants, deterioration of our; means of preserving and of increasing their therapeutic efficiency, 16.
Care, advantages of home over institutional, 692.
Carrel-Dakin treatment of infected wounds, observation of the, 338.
Carter, William Wesley: humped, hooked, and bulbous noses: their etiology and treatment, 872.
Catalase content, the, of the cerebrospinal fluid, 884.
Catarrh, acute suffocative, 814.
Cephalgia, permanent, following dysentery, 794.
Cerebellar abscess, report of two cases of, 499.
Cerebrospinal fluid in pertussis, 928.
Cerebrospinal fluid, the catalose content of the, 884.
Cesarean operation, the indications of the, 324; section, an address on the indications, for, 411; peritonitis, the prevention of, in a case of intrapartum infection subjected to extraperitoneal, 1080.
Cervix uteri, plastic conical enucleation of the, 966.
Chamberlin, Edwin C.: the after care of addicts, 1050.
Chancre of the tonsil, Vincent's angina simulating, 963.
Chapin, Henry Dwight: problems of boarding-out, with an attempted solution, 677.
Chemism, gastric, the clinical value of, 1004.
Chest, a partial review of the subject of military surgery of the, from the point of view of the experience of the world war, 1019; the late complications of gunshot wounds of, 28; the post influenzal, 1062; war wounds of the, 375, 1020.
Chiasmal lesions, surgical experience with an intracranial approach to, 934.
Child influenza at Geneva, 119; the etiology of neurotic symptoms in a, of eight, 969.
Childhood, gonorrheal infection in, 577; mental hygiene during, 561.
Children, a study of the stools of institutional, to determine the existence of intestinal parasitic infection, 87; acute cholecystitis in, as a complication of typhoid fever, 331; alimentation in, 158; chronic appendicitis in, 801; chronic infection of the facial and post-nasal lymphoid tissue in, 498; chronic intestinal stasis in, 157; chronic nephritis in, 850; circulatory reactions in normal, after exercise, 852; dental sepsis in: its consequences and treatment, 453; differential diagnosis of diseases of the hip-point in, 1089; gonorrheal vaginitis in, 1052; health classes for, 255; hyperchlorhydria — a frequent cause of defective appetitie in, 786; observations on tumors of the kidney in, 853; prolonged fever of undertermined origin in: report of cases, 736; some experiences with malaria among, in Palestine, 254; some remarks on cranial thrombosis in, 253; the energy metabolism of, from birth to puberty, 36; the incidence and significance of the rheumatic nodules in, 85; the treatment of indigestion in, 844, 845.
Chinese Red Cross, 958.
Chiropractor, practising medicine, 108.
Cholecystectomy, an improved technique for, based on an anatomical study, 893; the diagnosis of cholecystitis and indications for, 582.
Cholecystitis, acute, in children as a complication of typhoid fever, 331; the diagnosis of, and indications for cholecystectomy, 582.
Cholesterol metabolism of infants, a study of the, 35.
Chorea, Huntington's. Report of a case, 277.
Christian Science psychosis, the, 242.
Chromium salts and perforation of the nasal septum, 491.
Church, James Robb: ductless gland pathology in U. S. soldiers during the European War, 881.
Circulatory reactions in normal children after exercise, 852.
Clark, L. Pierce: an experimental study in mental therapeutics, 300.
Cleveland, Edward H.: some tuberculosis questions, 283.
Climenko, Hyman: the diagnosis of spinal cord tumors, 903.
Clinical research, 362; research, and address on, 368.
Coburn, Raymond C.: Anesthetics in obstetrics with special reference to nitrous oxide, 356.
Cocaine snuffing, perforation of the nasal septum from, 920.
Codeine poisoning, 491.
Colitis, ulcerative, operative treatment of, 843.
Colloidal gold test in multiple sclerosis, 149.
Colon bacillus, the rôle of the, in infections of the kidney, 586; human, yeasts from the. Protocol of laboratory studies as to pathogenicity, 693; surgical physiology and pathology of the, from the x-ray standpoint, 580.
"Common cold" the in relation to certain microorganisms, and its treatment with bacterial vaccines, 749.
Communicable disease, exclusion from school on account of, 875.
Congestion, passive hepatic, associated with high blood-pressure, 792.
Constipation, enemata of bile in, 1047; thyroidal, 452.
Constitutional question, a, 328.
"Contraction ring," the significance of the portion of a, in cases of extreme pelvic contraction with vertex presentation, 246.
Convulsions, a study of the relationship of, in infancy and childhood to epilepsy, 33.
Coroner's jury, verdict of, held not admissible in evidence to fit liability in civil suits, 833.
Correspondence, 115, 153, 154, 198, 242, 283, 328, 366, 367, 408, 493, 494, 620, 661, 703, 748, 881, 896, 1007, 1086, 1087; Geneva, 200, 365, 623, 840, 1010, 1050; London, 25, 75, 116, 198, 242, 283, 326, 408, 460, 459, 537, 574, 621, 659, 701, 746, 797, 882, 883, 923, 967, 1007, 1050, 1087; Paris, 26, 155, 747, 925.
Cosmetics of the visual apparatus, 928.
Coston, H. R.: a case of congenital hemi-hypertrophia totalis, 222.
Cotton, Henry A., Droper, John W., and Lynch, Jerome M.: intestinal pathology in the functional psychoses; preliminary report of surgical findings, procedures and results, 719.
Cough mixtures, glycerin substitute in, 424; tickling, 424.
Coughlin, W. T.: the maxillofacial service at A. R. C. M. H. No. 1, A. E F, France, 725.
Coyle, John G: clinical cure of malaria, 367.
Crance, Albert M.: differential diagnosis between the pains of tabes dorsalis and those of focal infection, 606.
Creosote inunctions in pneumonia and influenza, 676.
Criminality, mental deficiency and, 554.
Criminology, the study of, 21.
Crisis, the, in acute infectious diseases, 542.
Cross, Charles: feet, and rebuilding broken arches, 519.
Crutcher, Howard: a simplified and safer hysterectomy, 647; some observations on subperitoneal enucleation of the uterus; with a report of five cases, 1001.
Cumston, Charles Greene: a note on cases of sudden canaties in history, 609.
Curettage, uterine, a warning against promiscuous, 336.
Cutaneous hypersensitiveness, certain aspects of, 34.
Cyanosis, congenital, the pathogenesis of, 532.
Cycloplegia in routine refraction work, 971.
Cystoscopy, the value of, in cancer of the uterus, 1044.
Cysts, gas, of the abdomen, 203; hemic, of the spleen, 403; of the pancreas, 893; rapidly growing multilocular ovarian, associated with complete amenorrhea, 294.

D

Daland, Judson: observations on the epidemic of influenza occurring in the U. S. Naval Hospitals in Philadelphia in 1918, 173.

Dana, Charles L.: the career of Dr. Allan McLane Hamilton, 115; the late Dr. Joseph Fraenkel, 966.
Davenport, Charles B.: influence of the male on the production of twins, 509.
Davin, John P.: a constitutional question, 325; the legislative history of compulsory health insurance in the State of New York, 105; the narcotic and registration bills, 703; the unjust and burdensome registration law, 621.
Davis, Edward P.: infection of intestinal origin complicating pregnancy, labor, and the puerperal state, 551.
De Kraft, Frederic: action of electrical currents on ductless glands and other tissues, 136.
De Maupassant, the mental malady of, 836.
Death, by disease, accelerated by accident, does not warrant recovery on accident policy, 1081; cause of, accident hastening disease, 20; certificates, signature of, 192.
Debility, senile, treatment of, 1066.
Deficiency diseases, applied calcium therapy: a study of, 257.
Dengue: observations on a recent epidemic, 1040.
Dental defects, roentgen ray studies of, 466; infection in the production of nervous and mental diseases, 465; irritation, the medical aspect of, 704; sepsis in children: its consequences and treatment, 453; therapeutics based on clinical and roentgen ray investigations, 465.
Dextrocardia, massive congenital diaphragmatic hernia with, 713; the diagnosis of, 237.
Dextrose tolerance in atrophic infants, 87.
Diabetes and acidosis, the relation of glycogen to, 403; complicated by pulmonary tuberculosis, the treatment of, 811; curable, is? 802; and influenza, 1092; mellitus, the limitation of starvation in, 883; mellitus, diet reduction with retention of protein to relieve glycosuria in, 410; the drugless therapy of, 883; war rations, and, 79.
Diabetic patients, a consideration of surgical hazards in, 170.
Diagnosis, general internal, basal metabolism determinations in, 663.
Diaphragm, a case of anomaly of the, with a gastric and intestinal obstruction, 83; roentgenographic study of the, after intraabdominal inflation with oxygen. Preliminary report. 1094.
Diarrhea and vomiting, infantile; their prophylaxis and treatment, 927.
Diastolic pressure, the significance of the, 1029.
Dieffenbach, William H.: osteomalacia: is it a rare or a rather common disease? 995.
Diet reduction with retention of protein to relieve glycosuria in diabetes mellitus, 410; the, and health; amount and kind of food required, 947; the treatment and management of disease due to deficiency of; scurvy and beriberi, 331.
Dietaries, the effects of deficient on monkeys, 541.
Digestion, the surgical disorders of, 58.
Digitalis, clinical experience with a standardized dried aqueous extract of, 808; clinical observations of the absorption of, 464; in cardiac affections, 676; medication, notes on: absorption; variable susceptibility; rate of disappearance, 463; pharmacological study of Finnish, 79; principles, absorbability of certain, 463; principles of the new method of administering, 77.
Dinnan, James B.: concerning heliotherapy in tuberculosis, 62.
Diphtheria, an experience with the Schick test and toxin-antitoxin and a plea for their use in the extinction of, 286; convalescents, the problem of the "positive throat" in, 750; prevention of, 627; the Schick reaction for the determination of susceptibility to, 367; toxin, studies of the effect of, on the heart, 855.
Disease resulting from accident, 487.
Dispensary practice, 110; situation, the, in New York City, 180; situation in New York City, 204.
Diverticula of the bladder, 236.
Doctors, subsidizing the, 633.
Dorsey's magnesia solution, 340.
Dowd, J. Henry: the rôle of the neurones, 784.
Drainage, abdominal, 248; surgical, from a biological standpoint, 338.
Draper, John W., Cotton, Henry A., Lynch, Jerome M., and: Intestinal pathology in the functional psychoses; preliminary report of surgical findings, procedures and results, 719; Lynch, J. M., and: yeasts from the human colon. Protocol of laboratory studies as to pathogenicity, 693.
Dreams, 275; of the feeble-minded, 395.
Dried-milk feeding, 550.
Drugs, habit-forming, keeping duplicate prescriptions of, 612; narcotic, and state legislation, 663; prohibited, evidence of good faith in dispensing, 917.
Ductless gland pathology in U. S. soldiers during the European War, 881; and constitutional diagnosis, 558; and other tissues, action of electrical currents on, 136; see also *Endocrinology*.
Dunham, Kennon: localization of pulmonary lobes by the *x*-ray, 1077. 1094.
Duodenal perforation (fistula) treated by duodenal (jejunal) alimentation, 578.
Duodenum, a congenital anomaly of the, and its surgical significance, 248; stomach and, the late results of the surgical treatment of chronic ulcers of, 750.
Dwarf, the metabolism of a, 842.
Dying declarations, 531; as evidence. 192.
Dysentery, amebic, the status of, with special reference to diagnosis and treatment, 288; permanent cellalgia following, 794; surgical aspect of, 663.
Dyspnea and early death in arteriosclerosis, 279.

E

Earp, Samuel E.: concerning rheumatic and some other infections, with illustrative cases, 1074.
Eczema, 1023; acute, 646; as a defense reaction, 195; the predominance of seborrheic, in early life, 83; treated by rectal saline injections, 424.
Ectropian of the os uteri, 542.
Ehrlich, Simon D.: the present status of general anesthesia from the hospital viewpoint, 651.
Einhorn, Max: on retrograde stretching in the treatment of impermeable cardiospasm, 983.
Embolus, a German bullet, 246; in the femoral artery removed by operation, 498.
Embryology and surgery, 338.
Emetine, dysenteric abscess of the liver cured by, 117.
Empathic index, the, and personality, 131.
Empyema, acute, a series of one hundred consecutive cases of, 1056; acute, observations on the relative value of the various operative procedures employed in, 975; at Base Hospital, Camp Mills, with special reference to the use of Philips' empyema apparatus, 40; at the Cincinnati General Hospital during the influenza epidemic, 335; cases treated at the Rockefeller War Demonstration Hospital, New York, 1056; chronic, exploratory thoracotomy for, 374; new problems in, 1057; the surgical treatment of, 249; the treatment of, 1057; the treatment of, in the Army, 1057; with particular reference to its pathogenesis and treatment, 418.
Encephalitis, acute epidemic, 770; lethargica, 494; epidemic, differentiation between influenza and, 1048; epidemic, the diagnosis of, 926; epidemics (miscalled lethargica), with special reference to diagnosis, 994; lethargica, 532, 624, 712, 815, 841, 843, 919, 925; lethargic, ambulatory cases of, 993; autoserum therapy (intraspinal) in, 1079; lethargica diagnosticated as cerebral influenza, 362; lethargic, did Sydenham describe? 615; lethargic, histological differentiation of, 982; lethargica in England, 322; lethargica in pregnancy, 540; lethargic, meningeal hemorrhage in, 971; lethargica, polymorphism of, 613; myelitic form of lethargic, 885; myoclonic, 835; post-influenzal, 37.
Encephalomyelitis epidemica, 706.
Enchondroma of the lung, 623.
Endocarditis, malignant, 690.
Endocrine diseases, symposium on, 623; dyscrasia, arterial hypertension associated with, 812; treatment in the sterility of women, 121; in gynecology, an introduction to the, 411; influenza as a pulmonary necrotic alveolitis involving the, 926; the balance between the, and in each individual endocrine, 638.
Endocrinology and gynecological practice, 120; medical aspects of, 511; see also Ductless glands.
Endometrium, relation of hyperplasia of the, to so-called functional uterine hemorrhage, 889.
Enema, historical notes on the, 1101; retention, the administration of arsphenamine by, 144.
Enemata of bile in constipation, 1047.
Energy metabolism of children from birth to puberty, 36.
Engstrom, Otto, death of, 1066.
Enterorenal syndrome, the, 971.
Enuresis treated by dietetic and hygienic measures, 340.
Enzyme, proteolytic, on the, of fibrin, 625.
Epilepsy, a study of the relationship of convulsions in infancy and childhood to, 33; and anaphylaxis, 159; anosmia and, 1008; is essential, hereditary? 571; new conception of, 119.
Epithelioma of the jaw, 764.
Epstein, J.: amaurotic family idiocy or infantile amaurotic idiocy, 224.
Erdmann, John F.: surgery of the gallbladder, 901.
Esophagoplasty, superior, for inoperable cancer of the lower portion of the esophagus and of the cardia, 1099.
Esophagus, removal of a vertebra of a chicken from the, 959; superior esophagoplasty for inoperable cancer of the lower portion of the, and cancer of the cardia, 1098; the treatment of cicatricial stenosis of the, 1099; ulcer of the, from the standpoint of an esophagoscopist; its cause, symptomatology, diagnosis and treatment, 319.
Euphorbia serpens as a dechloridizer, 213.
Evidence, opinion, as against positive testimony, 1043.
Exophthalmos of hyperthyroidism, loss of both eyes from the, 799.
Expert evidence as to existence of typhoid fever, 1002; electric voltage sufficient to cause death, 108; fracture cases, 402.
Expert testimony as to cause of condition, 359; as to permanency of injuries, 235; hypothetical questions and personal knowledge, 791; only, of weight as to proper performance of surgical operations, 740.
Expert witnesses, cross-examination of, 192.
Extremities, acrocephaly with deformities of the, 84.
Eye, as a portal of infection in respiratory diseases, 411; in pregnancy, 286.
Eyes, artificial, in antiquity, 1100; loss of both, from the exophthalmos of hyperthyroidism. 799.
Eyesight, miners, 496.

F

Family, the matriarchal, 918.
Fascia lata, the uses of free transplants of the, in surgery. 331.
Fatigue, acetonuria of, 571.
Feeble-minded, dreams of the. 395.
Feeding, maternal, of infants, 814; maternal, three pertinent questions on, 847.
Feet, and rebuilding broken arches, 619.
Female, prolapse of the urethra in the, 892.
Femur, artificial impaction of the, in the aged, 247; fracture of the: a plea for a better American standard, 977; fractures of, see *Fractures*; gunshot fracture of the, 416.
Ferments, what are? 289.
Fever, prolonged, of undetermined origin in children: report of cases, 736.
Fibrillation, auricular, a case of, in a young girl, 708.
Fibrin, on the proteolytic enzyme of, 625.
Fibroids, cancerous degeneration of, following radiotherapy, 370; uterine, an analysis of cases of, treated by abdominal subtotal hysterectomy, 202.

Finland, morbidity of, in May, 79.
Fischberg, Maurice: diagnostic pitfalls in pulmonary tuberculosis, 89.
Fistula, arteriovenous, the effect of, upon the heart and blood vessels, 801; vesicovaginal, the operative treatment of, 249.
"Flat foot" and other static foot troubles, 118.
Fleas and contagion, 751.
Fluid injection in dehydrated infants, 711.
Focal infection and its relation to obstetrics, 624; differential diagnosis between the pains of tabes dorsalis and those of, 606; the relation of, to mental disease, 841; in what way do, cause systemic disease? 999; of the genitourinary tract, constitutional symptoms and, 289; of the head as sources of systemic diseases, 353; the end results of, 855.
Food dislikes, acquired, the relation of, of childhood to the ills of middle life, 846.
Foods, baby, the antiscorbutic value of proprietary, 855; do calories measure the value of, 78, 86; factors, accessory (vitamines) in the feeding of infants, 884; factor, accessory, on the relation of the lipochrome pigments to the fat-soluble, 885.
Foot, weakened: its measurement and correction, 681.
Foreign bodies in the air and food passages, 32; in the bronchi, the physical signs of, 541.
Fractures, application of the methods developed during the war to the fractures of civil life, 585; due care and skill in setting, 320; gunshot, observations after severe, of the long bones, 598; gunshot, of the femur, 416; mechanical stability of, following operation, 977; of long bones, autogenous bone grafting for repair in, 339; of the femur: a plea for a better American standard, 977; of the humerus treated by traction, 168; of the mandible, mobilization of, 743; of the posterior tubercle of the astragalus vs. inconstant os trigonum, 1011; of the skull, civil lessons of the war for the treatment of, 1013; some rarer, 247; the abduction treatment of, of the neck of the femur, 585.
Fraenkel, Dr. Joseph, the late, 966.
Frantz, Morris H.: Huntington's chorea. Report of a case, 277.
Fredet-Rammstedt operation, the, congenital hypertrophic pyloric stenosis in infants: review of 175 cases in which, was performed, 936.
Frost-Lang operation, the, 1012.
"Full-time men" and general practitioners, 613.

G

Gall-bladder pathologies, chronic, the diagnosis of, 889; pathologies, chronic, the diagnosis of, 930; some special points in the surgery of the, 584; surgery of the, 901.
Gallstone disease, operation and reoperation for, 749; disease, the prophylaxis and treatment of, 869.
Gangrene of the lung, treatment of, 841.
Gas gangrene in typhoid fever following hypodermic infusion, 339; illuminating, child poisoned with, by its insane mother, 703; poisoning, brain lesions in, 766.
Gasserian ganglion, the injection of the, for neuralgia and other conditions, 334.
Gastrectomy, a new technique for, 376.
Gastroenterostomy, a successful posterior, 76 hours following a Rammstedt operation which failed to relieve the obstruction, 337; ulcer of the jejunum, 937.
Gastrointestinal abnormalities, a few roentgenograms demonstrating, 84; disease, practical clinical laboratory diagnosis in, 666; disease, symposium on, 666; tract, dietetic treatment of disease of upper, 667; tract, drug treatment of disease of upper, 668; tract, perforation of, 338; tract, practical clinical examination of the upper, 666.
Genitourinary tract, constitutional symptoms and focal infections of the, 289.
Gilmore, Albert F.: the Christian Science psychosis, 242.
Ginsburg, Solomon: reflex phenomena in a recent series of influenza cases, 98.
Glycogen, the relation of, to diabetes and acidosis, 403.
Glycosuria, renal, 810.
Glanders a disease, not an accident, 147.
Glands, ductless, and other tissues, action of electrical currents on, 136.
Glandular insufficiency in pediatrics, 158.
Glaucoma, the diagnosis of, 578.
Goiter, cystic, drainage and the mercury ion in, 799; exophthalmic, surgical treatment of, 419; exophthalmic, surgical treatment of, 670; injection method of treating, 340; one hundred, operations: mistakes in retrospect, 932; surgery, practical points in, 669; symposiums on, 669.
Gold, colloidal, test in multiple sclerosis, 149.
Gonococcus infection, sensibilization of mucous membranes of the guinea pig to, 369.
Gonorrhea, internal medication in, 550.
Gonorrheal infection in childhood, 577; infections, a new method of treating remote manifestations of, 190.
Goodman, Herman: the prostitute in jail: an opportunity for public health work that gives results, 483.
Gout: a clinical study of 116 cases, 809.
Grafts, the use of bone and fascia, in the reconstruction of bones and joints, 977.
Graphic measurements of operative results, 295.
Graves' disease, syphilis and, 698.
Graves, William Washington: some principles seldom recognized in the treatment of syphilis and the syphilitic, 1025.
Great Britain, falling birth rate in, 242; industrial medicine in, 116; national compulsory insurance and the medical profession in, 283; preventive medicine in, 70.
Greeley, Horace: blood counts in diagnosis and treatment, 348.
Greenberg, David: prolonged fever of undetermined origin in children: report of cases, 736; some unusual symptoms and signs observed in the last influenza epidemic, 188.
"Gridiron" incision, the frequency of right inguinal hernia after appendicectomy by the, 78.
Grippe, cause of death in, 298; in Warsaw, 1005; Japanese human experiments on the contagion of, 656; mental disease cured by, 111; nervous and mental complications of, 794; the earliest epidemic of, 1013; virus, nature of the, 111.
Grossman, Jacob: interesting cases from the orthopedic clinic of Lebanon Hospital, 309; oral sepsis and the rôle it plays in certain orthopedic conditions, 514.
Group study from the standpoint of the internist, 972; study in urological and gynecological surgery, 974; study, some remarks on, in the surgery of the head, 972.
Growth and equilibrium, complemental factors of, 369.
Gunshot wounds, see *Wounds*.
Gutman, Jacob: the ductless glands and constitutional diagnosis, 558.
Gwathmey, James Taylor: the anesthesia problem in lung surgery, 987.
Gynecological patient, the, of the general practitioner, 635.
Gynecology, an introduction to the endocrines in, 411; and obstetrics at Strasbourg, history of, 718; roentgen therapy in, 207.

H

Haberman, J. Victor: the measure of intelligence diagnostically remeasured, 467, 523.
Haines, W. D.: the surgical disorders of digestion, 58.
Hall of Fame, no physician or surgeon as yet in the, 620.
Hamilton, Allan McLane, the career of, 115.
Hand, a clinical study of infections of the, 1053.
Hare, John H.: Hippocratic medicine, 313.
Harriott, C. Carman: practice of hygiene in place of preaching, 748.
Harrison narcotic act—intent in selling morphine, 960.
Hay fever, the specific treatment of, 576.
Head, some remarks on group study in the surgery of the, 972.
Headache, rhinogenic, 203.
Health classes for children, 255; commission, international, 494; insurance, 621; insurance, community health units and, 103; insurance, compulsory, 290; insurance, opposition to compulsory, 150; insurance, the legislative history of compulsory, in the State of New York, 105; officers, authority of to make regulations, 740 public, see *Public health;* representations as to, and consultations in insurance application, 531; study, a, in a boys' school, 82; testimony as to, of insured persons, 791; the diet and; amount and kind of food required, 947; the ministry of, and its consultative medical committees, 199; welfare, nationalization of the agencies for the, of the people, 628; work in Jerusalem, 214.
Hearing, every-day problems in conserving the, 331.
Heart, a case showing apparent paradoxical respiratory arrhythmia of, 969; action, disordered, mineral salts for, 1007; and blood-vessels, the effect of arteriovenous fistula upon the, 801; block, a case of complete, 708; block: a record of twenty cases, 927; block, would the intraspinal injection of a solution of calcium salts cause instant? 408; diseases, acute, death in, 159; disease and its treatment, 659; disease, newer ideas of, applied to pediatrics, 851; disease, the diagnosis of, in young people, 452; malformation, congenital, a specimen of, 708; psychoanalysis of the, 568; studies of the effect of diphtheria toxin on the, 855; the aviators; Roentgen ray studies under conditions simulating high altitudes, 1098; the volume of, 404.
Heat, extreme, effect of blow while working under, 960.
Heliotherapy in tuberculosis, concerning, 62; Rollier's, surgical experience with tuberculosis of the joints, 247.
Helium, 23.
Hemangioma and lymphangioma: their response to the injection of boiling water, 935.
Hematuria, a case of scorbutic, 83.
Hematochyluria, a case of non-parasitic, 332.
Hemihypertrophia totalis, congenital, a case of, 222.
Hemiplegics, the re-education of, and their physiotherapeutic treatment, 969.
Hemorrhoids, internal, the standardization of operations for, 1090.
Hemmeter, John C.: the evolution of recent investigations concerning the water metabolism of the body in relation to the digestive secretions and the functions of the blood, 858.
Hemorrhage and stricture of the urethra, 971; cerebral, the coagulation time of the blood in the new-born, with special reference to, 854; delay postoperative, following tonsil and adenoid removal, an unusual case of, 832; prenatal, 615; relation of hyperplasia of the endometrium to so-called functional uterine, 889; uterine, radium treatment of, 141.
Hemostasis obtained with small rubber bands instead of ligatures, 245.
Henry, Alfred: prognosis in pulmonary tuberculosis, 272.
Heredity as a factor in the etiology of neoplasms, 14.
Hernandez, Dr., of Venezuela, death of, 940.
Hernia, diaphragmatic, 248; diaphragmatic congenital, with report of a case, 335; diaphragmatic, congenital, 714; diaphragmatic, massive congenital, with dextrocardia, 713; epigastric, the symptoms and differential diagnosis of from gastric ulcer, 741; local anesthesia in the radical cure of, 274; of the ovary, 890; proof of cause of, 359; the frequency of right inguinal after appendicectomy by the "Gridiron" incision, 78; the value of position in the operative treatment of, 583.
Heredity, 926.
Hertz, Julius J.: medical aspects of endocrinology, 511.
Hiccough, persistent, 382.
Hill, Miner C.: advantages of home over institutional care, 692.
Hip-joint, differential diagnosis of diseases of the, in children, 1089.

Hoag, David Edward: the management of certain mental and nervous cases; a medicolegal aspect, 910.
Holmes, Oliver Wendell, and the medical student, 1067.
Holt, L. Emmett; home vs. hospital care of cases of influenza, 731.
Hospital, American, in London, 1050; practical application of methods of standardization of the, 576.
Hospitals, standardization of, 422.
"House burials" in Macedonia, 413.
House-fly, the importance of the, as a carrier of E. hemolytica, 412.
Hubbard, Ernest V.: an unusual case of delayed postoperative hemorrhage following tonsil and adenoid removal, 832.
Humerus, fracture of, treated by traction, 168.
Hunt, Edward Livingston: encephalitis lithargica, 815.
Huntington's chorea. Report of a case, 277.
Hurley, John J: Influenza and sinusitis, 153.
Hutchins, Charles Pelton: Weakened foot: its measurement and correction, 681.
Hydatid disease in Uruguay. 1100.
Hydroceles, spermatoceles and, containing spermatozoa, 334.
Hydrochloric acid, the pharmacology of, 698.
Hydronephrosis, right, 37.
Hygiene, mental, during childhood, 561; practice of, in place of preaching, 748.
Hyman, Albert S.: radiography in artificial pneumoperitoneum, 100.
Hyperchlorhydria—a frequent cause of defective appetite in children, 786; and air swallowing, a clinical lecture on, 118.
Hyperpyrexia, heat, the nature, prevention, and treatment of, 705.
Hypersensitiveness, cutaneous, certain aspects of, 34.
Hypertension, arterial, 497; arterial, associated with endocrine dyscrasia, 812; arterial, the relation of, to nephropathies, 475; vascular, renal function and, 663.
Hypertensive states, use of relaxation in, 538.
Hyperthyroidism, a symptom of, 362; differentiation of tuberculosis from, 670; loss of both eyes from the exophthalmos of, 799; surgical treatment of; relation existing between the amount of gland removed and the permanence of relief, 670.
Hypodermic injections of purgative drugs, 21.
Hypodermoclysis, 334.
Hypothetical questions, 487.
Hysterectomy, a plea for total, in the operative treatment of fibroid tumors of the uterus in parous women, 889; a simplified and safer, 647.
Hysterical symptoms: modes of induction in war and peace; suggestion in maniacal simulators, 1.

I

Ictus, amnesic, diagnosis and prognosis of the, in general paresis, 193.
Idiocy, amaurotic family, or infantile amaurotic idiocy, 224.
Ileostomy for postoperative obstruction following appendectomy, 337.
Illegitimacy, the problem of, and the state care of its child population, 702.
Incisions, abdominal, 581.
Indigestion in children from six to twelve years of age, the treatment of, 845; in children, the treatment of, 844.
Infancy and childhood, local anesthesia in, 856; and childhood, the clinical value of vegetable oils in certain abnormal conditions of, 848; and early childhood, the prevention of respiratory diseases in, 817; enlarged thymus gland in, and its treatment by radium, 77; intestinal toxemia in: a suggested explanation, 163; pyloric stenosis of, 801; thick cereal feeding in malnutrition in, 162.
Infant feeding in Vienna, 200.
Infantile spinal progressive muscular atrophy (Werdnig-Hoffmann), 851.
Infants, a study of the cholesterol metabolism of, 35; accessory food factors (vitamines) in the feeding of, 884; and children, isoagglutinins in the blood of, 697; and children, transfusion in: the indications and dangers, 36; certain nutritional disorders in, associated with proteolytic intestinal flora, 35; dehydrated, fluid injections in, 711; dextrose intolerance in atrophic, 87; male, the greater delicacy of, 569.
Infection, gonococcus, sensibilization of mucous membranes of the guinea pig to, 369; gonorrheal, in childhood, 577; intestinal parasitic, a study of the stools of institutional children to determine the existence of, 87; of intestinal origin complicating pregnancy, labor, and the puerperal state, 551; oral, and mental disease, 22; see also *Focal infection.*
Infections, concerning rheumatic and some other, with illustrative cases, 1074; focal, of the genitourinary tract, constitutional symptoms of, 289; focal, of the head as sources of systemic diseases, 353; gonorrheal, a new method of treating remote manifestations of, 190; postabortive and puerperal, the policy of noninterference in the treatment of, 891.
Infectious diseases, acute, the crisis in, 542; diseases, remedial measures conservative in most acute; in particular for adults and during influenza, 268.
Inflammation, pelvic, the operative treatment of, 336.
Influenza. A confirmatory report upon the abortive action of quinine dihydrochloride, 235; a new remedy for? 154; aequanimitas and, 278; an echo of, 23; and sinusitis, 153; and tuberculosis, 250; and tuberculosis, the relationship between, 490; as an etiological factor in nephritis, 625; as a pulmonary necrotic alveolitis involving the endocrines, 926; case of, complicated with streptococcic bronchopneumonia, endocarditis, arthritis, and pyemia; with recovery, 1042; cases, reflex phenomena in a recent series of, 98; child, at Geneva, 119; complement-fixation experiments in, 497; cycle, is there an? 236; diabetes and, 1092; differentiation between, and epidemic encephalitis, 1048; eliminative treatment of, 382; epidemic, some unusual symptoms and signs observed in the last, 188; epidemic, the Argonne, 460; etiology and pathogenesis of, 971; etiology and treatment of, 446; home vs. hospital care of cases of, 731; in Switzerland in 1920, 1092; infection, 246; is a spirochetosis? 30; manifestations of, during the earlier periods of its appearance in France, 459; observations on the epidemic of, occurring in the U. S. Naval Hospitals in Philadelphia in 1918, 173; or epidemic sepsis, 280; pandemic, date of origin of the, 71; pandemic, retrospect of the, 150; pandemics, the genus epidemicus of, 530; patients, experimental study of the nasopharyngeal secretion from, 1012; plague and, 538; pneumonia, 370; pneumonia and, creosote inunctions in, 676; preventive treatment in, 29; psychic disturbances in, 840; retrospect of, 743; the cause, prevention, and cure of, and allied diseases, 481; the pandemic of, as it affected Canton, China, 391; the pandemic of, in Iceland, 1054 the practical aspects of quarantine for, 119; the relation of the influenza bacillus to, 1015; the relation of Pfeiffer's bacillus to, 202; the treatment of, 198; treatment of, by an apparently specific method, 66.
Influenza-pneumonia, is, contagious? 877.
Influenzal pneumonia: the intravenous injection of hydrogen peroxide, 540.
Inhalation treatment in pulmonary tuberculosis, 143.
Injury, medical expert's answer as to permanence of, 740.
Insane, care of in Syria, 742.
Insanity among the Jews, 30; manic depressive, and Raynaud's disease, 694.
Insurance application, false answers in, 192; health, see *Health insurance;* national compulsory, and the medical profession in Great Britain, 283.
Intelligence, the measures of, diagnostically remeasured, 523; the measure of, diagnostically remeasured, 467.
Internal secretions and vitamines, 741; secretion of sex glands, disturbance of, 632.
Internist, group study from the standpoint of, 972.
Intestinal invalid, chronic, the mental factor in the, 452; obstruction, 841; obstruction, unusual care of, 843; pathology in the functional psychoses; preliminary report of surgical findings, procedures and results, 719; toxemia in infancy: a suggested explanation, 163; toxemia—its medical and surgical treatment, 398.
Intestine, large, surgery of cancer of, the, 937.
Intoxication, rôle of, in the genesis of psychoses, 1005.
Intracardiac pressure as a standard in cardiotherapy, 970.
Intussusception, acute; report of a case relieved by enema, 821; resulting from benign tumor of the intestine: report of three cases, 338.
Inventions, medical, for the protection of ideas and, 112.
Isham, Mary K.: a case of mixed neurosis with some paraphrenic features, 990.
Isoagglutinins in the blood of infants and children, 677.
Intubation of the larynx, 852.

J

Janis, Aurelius R. de: psychoanalysis of the heart, 568.
Japanese human experiments on the contagion of grippe, 656.
Jaundice and its surgical significance, 248; splenomagalic hemolytic: case report for congenital type, 864.
Jaw, epithelioma of, 764.
Jews, insanity among the, 30.
Joints, stiff and flail, 419; surgical experience with tuberculosis of the; Rollier's heliotherapy, 247; Willems' method of active mobilization in surgical, 357.
Journalism, medical, early Spanish, 130.
Jugular vein, deep cervical abscess and thrombosis of the internal, 502.

K

Kahn, Alfred: The cause, prevention, and cure of influenza and allied diseases, 481.
Kane, Elisha Kent, in memory of Dr., 618.
Katz, Joseph: Deficient thyroid secretion as an etiologic factor in gastric and duodenal ulcers and in hyperacid conditions, 916.
Kennedy, Thomas C.: Radium treatment of uterine hemorrhage, 141.
Kennell, L. A., Wright, B. L., and: A preliminary report on the use of a new arsenical compound in the treatment of syphilis: "Monarsone," 607.
Kerley, James Hoyt: Hyperchlorhydria—a frequent cause of defective appetite in children, 786.
Kidney, cystic, a type of, amenable to surgical treatment, 586; fused. Right hydronephrosis. Resection. Recovery, 37; observations on tumors of the, in children, 853; polycystic, of atypical character, 735; squamous cell carcinoma of the, 935; stone in the, 336; syphilis of, 813; the role of the colon bacillus in infections of the, 586.
King, James Joseph: Focal infections of the head as sources of systemic diseases, 353; Elmer H.: The cancer problem. A contribution toward its solution, 444.
Kinks, ureteral, and their significance, 437.
Kirkwood, R. C.: does community responsibility end when sanatorium treatment has been given?, 738.
Knopf, S. Adolphus: No physician or surgeon as yet in the Hall of Fame, 620; the antituberculosis movement in the United States prior to and since the formation of the National Tuberculosis Association. With brief tributes to its departed leaders, 1071; William T. G. Morton the discoverer and revealer of anesthesia, and his place in the Hall of Fame, 1086.
Koenig, C. J.: Mycotic otitis, 956.
Koopman, John: Serological technique, 1035, 1036.

L

Labor, gangrenous appendicitis coincident with, 166.
Lactation, abnormal, 890; menstruation and, 876; temperature of the mammæ at the onset of, 921.
Laennec as a poet, 1083; centennial, 27; the professorship of medicine held by, in the University of Paris, 69; unpublished notes by, on hepatic cirrhosis, 413.
Lamp, a shadowless, 925.
Langstroth, Francis Ward: Plastic conical enucleation of the cervix uteri, 966.
Laparotomy, value of different incisions for, 369.
Larva of an insect (alaus oculatus), remarkable vitality in the, 874.
Laryngectomy, total, a note on the later history of four cases of, 705.
Larynx, intubation of, 852.
Lavage, pelvic, for pyelitis, 210; spinoventricular, in the treatment of meningitis, 569.
Laveson, H.: Compulsion neuroses (obsessions, doubts and phobias), 790; dreams, 275; lapsus of memory, 106; psychonanalysis, 952; symbolism, 649.

Opium, purchase of, by registered physician for personal use, 875.
Oral infection and mental disease, 22.
Oral sepsis and the rôle it plays in certain orthopedic conditions, 514; the present status of, in relation to sys-

temic disease, 465; the present status of, in relation to medical diseases, 749.
Orientation, rapid, in reflexes, 150.
Orthopedic clinic of Lebanon Hospital, interesting cases from the, 309.
Os trigonum, inconstant, fracture of the posterior tubercle of the astragalus vs., 1011.
Osteitis, gummatous, of the skull, the surgical treatment of, 330; tuberculous, high frequency and high tension in the treatment of, 543.
Osteogenesis imperfecta-congenita, 85.
Osteomalacia: is it a rare or rather common diease? 995.
Osteomyelitis, acute staphylococcic, vaccinotherapy in, 324.
Otani, Morisuke: a new method of phagocytosis test, with the blood plasma, a specific immunological reaction, 439.
Otitis, mycotic, 956.
Oto-laryngology, the value of laboratory examinations in diagnosis and prognosis in, 7.
Ouabaine, diuretic action of, 277.
Ovarian autointoxication, 203.
Ovaries, animal, results of the exposure of, to the rays of radium, 890.
Ovary, hernia of the, 890.
Oxycephaly; its occurrence in negroes, 807; report of two cases, with decompression operation in one, 339.
Oxygen, a roentgenographic study of abdominal organs after intraperitoneal inflation with, 209; roentgenographic study of the diaphragm after intraabdominal inflation with. Preliminary report, 1094; inflation of the peritoneal cavity, 705; intrauterine insufflation of (artificial pneumoperitoneums) for the determination of the patency of the fallopian tubes in cases of sterility, 890.

P

Pain, abdominal, spondylitis and, 809; right-sided abdominal, unraveling the mysteries of, in the female, 336.
Pains, differential diagnosis between the, of tabes dorsalis and those of focal infection, 606; right iliac fossa, remarks on the diagnosis of, and the end results of 200 operations for chronic appendicitis, 579.
Palermo, Anthony M.: anesthesia in cerebral and spinal surgery, 231.
Palsy, brachial birth, a pseudo-paralysis of shoulder-joint origin, 123.
Pancreas, cysts of the, 893; the diagnosis of diseases of the, 800.
Pancreatic insufficiency, alimentary anaphylaxis from, 657; insufficiency, Loewi's adrenalin mydriasis as a sign of, 1054.
Pandemic, the, of 1918, 289.
Panel practice, 199; criticisms of, 882.
Pantoponism, 159.
Paralysis agitans, cacodylate of soda in, 615; obstetric—its cause and treatment, 413.
Paratyphoid B. group, the, 287.
Paresis, a special strain of spirochete the cause of, 466; general, diagnosis and prognosis of the amnesic ictus in, 193.
Park, Francis E.: treatment of influenza by an apparently specific method, 66.
Parotitis, nervous complications of, 155.
Passive movements, the abuse of, 368.
Pediatrics, glandular insufficiency in, 158; is, a specialty? 404.
Pellagra, etiology of, 962; experimental, 1003; outbreak, the, in Egypt, 970; outbreak in Egypt—pellagra among German prisoners of war, 1012; types and treatment of, 804.
Pepsin, 340.
Peptone treatment of asthma, results of the, 928.
Percussion, the physics of, 958.
Perforation, duodenal (fistula) treated hy duodenal (jejunal) alimentation. 578.
Pericolitis, membranous, the pain of, 840.
Peritonitis, septic, the treatment of, 885; peritonitis, the prevention of, in a case of intrapartum infection subjected to extraperitoneal Cesarean section, 1080
Perkins, C. Winfield: observations after severe gunshot fractures of the long bones, 598.
Personality, the emphatic index and, 132.
Pertussis, cerebrospinal fluid in, 928.
Pfeiffer's bacillus, the relation of, to influenza, 202.
Phagocytosis test, a new method of, with blood plasma, a specific immunological reaction, 439.
Pharmacopœial Convention, 239.
Philips' empyema apparatus, empyema at Base Hospital, Camp Mills, with special reference to the use of, 40.
Phlebectasis of the diaphragmatic area and of the lower thoracic and upper abdominal regions, 806.
Physical therapy in military and civil practice, 321.
Physician and surgeon of the industrial era, 421.
Physician's charges, 402; deposition as evidence, 791; home, the, 614; opinion, basis of—medical works in evidence, 191.
Physicians and surgeons, a world congress of, 410; the murder of, 614.
Phosphoric acid, 623.
Pigments, lipochrome, on the relation of the, to the fat-soluble accessory food factor, 885.
Pilomotor reflex, the, 743.
Pineal gland, comments on the function and clinical uses of the, 12.
Placenta prævia, an analysis of one hundred cases of, 550.
Plague and influenza, 538; rats and the, in Senegal, 802; the, at Avignon in 1721, 793.
Pleurisy, prevention and treatment of, 975; the diagnosis of encysted tuberculosis, of the apex, 278.
Pneumonia and influenza, creosote inunctions in, 676; experimental, 876; influenza, 370; influenzal: the intravenous injection of hydrogen peroxide, 540; influenzal, the pathology of, 1003; lobar, the prevention and serum treatment of, 1014; the integrity of the vagus nerves as a factor in, 1095; the nephritis of, 962.
Pneumoperitoneum due to perforated gastric ulcer, x-ray of, 171 radiography in artificial, 106; roentgenologic experience with, 938.
Poise and tranquillity a neccssary condition of economic repair, 780.
Poisoning, delayed arsenical, 842; industrial, 76.
Poisons, alimentary, 1054.
Poland, the new medical, 794.
Polymorphism of encephalitis lethargica, 613.
Positions, the treatment of obstinate occipitoposterior, 891.
"Positive throat" in diphtheria convalescents, the problem of the, 750.
Postinfluenzal chest, the, 1062.
Pott's disease, the diagnosis of syphilitic suboccipital, 360.
Practitioners, general, "full-time men" and, 613; general, the gynecological patient of the, 635.
Pregnancy, ectopic, 548; ectopic, a clinical study of; a new etiological theory, 478; encephalitis lethargica in, 540; following radiotherapy of fibroid uterus, 1034; in the rudimentary horn of a bicornate uterus, 293; labor and the puerperal state, infection of intestinal origin complicating, 551; the eye in, 286; the relation of malaria to, 28; the rôle of carbohydrates in the treatment of toxemias of early, 577; the symptomatology of extramembranous, 109; unruptured tubal—seventh week, 164.
Pressure, diastolic, the significance of, 1029.
Preventable diseases of adult life, 626.
Preventive medicine in Great Britain, 70.
Priority of ideas relating to medical subjects. On the desirability of instituting a special medical board which should correspond to the Patent Office: the function of this medical board being to establish and protect the, 227.
Privileged communications, 320; in criminal cases, 235; statutes, 147; waiver—conversations after relations have ceased, 833.
Pro-German naïvetés, 843.
Prostate, surgical and non-surgical treatment of the, and seminal vesicles in arthritis, 587.
Prostatism, 244.
Prostitute, the, in jail: an opportunity for public health work that gives results, 483.
Proteal, serum sickness treated with, 487.
Proteinotherapy, 30.
Proteins, disturbances caused by, 925.
Pruritus of the vulva and anus, an operation for, 892.
Pseudoanemia, 200.
Pseudohermaphrodism, masculine, with normal vagina, 239.
Pseudology, epidemicological, 72.
Pseudomyxoma peritonei 335; in male subjects, 335.
Psoriasis, internal remedies in, 361.
Psychoanalysis, 952; of the heart, 568.
Psychoneuroses, the somatic causes of, 800.
Psychopathies and neuropathies of cardiovascular diseases, 704.
Psychoses, functional, intestinal pathology in the; preliminary report of surgical findings, procedures and results, 719; rôle of intoxication in the genesis of, 1005.
Psychosis, the Christian Science, 242.
Psychopathology, historical beginnings of, 802.
Psychotherapy in practice, 157; and morphine addiction, 1084.
Public health problems, the significance of some general biological principles in, 330.
Pulmonary lobes, localization of, by the x-ray, 1077, 1095; suppurations, 1096.
Purgative drugs, hypodermic injections of, 21.
Pyelitis, pelvic lavage for, 210; two cases of, and a case of suppression of urine for four days, 84.
Pyloric stenosis, congenital hypertrophic, in infants: review of 175 cases in which the Fredet-Rammstedt operation was performed, 936; stenosis of infancy, 801.
Pyramidal tract, a new phenomenon of the, 369.

Q

Quackenbos, Maxwell: Clinical indications for enucleation of the faucial tonsil, 653.
Quarantine regulations, validity of, 487.
Quantitative methods, the influence of, in the advance of clinical medicine, 809.
Query, the treatment of syphilis by the antisyphilitic serum of, 927.
Quinine, adrenalin and, antagoism of, 313; dihydrochloride, see *Influenza*.
Quinsy, the use of antistreptococcic serum, in, 664.

R

Rabies, anatomical diagnosis of, 690; differential diagnosis of, 940.
Radiography in artificial pneumoperitoneum, 100.
Radium and cancer, 198; enlarged thymus gland in infancy and its treatment by, 77; the therapeutic value of, 206; the treatment of malignant tumors of the thymus by, 1094; therapy of cancer of the uterus, 369; treatment of cancer of the uterus, late results in the, 202; treatment of uterine hemorrhage, 141.
Rashes, scariatinoid, clinical interpretation of, 496.
Rats and the plague in Senegal, 802; war on, 116.
Raynaud's disease, manic-depressive insanity and, 694.
Reactions, electrotonic, of Abrams, avert pneumonia, 565.
Reconstruction of workmen after injury, 576.
Rectum, aseptic amputation of the, 168; cancer of the, 370; carcinoma of the, operation for, 937; some plastic operations on the, 339.
Red Cross, Chinese, 958.
Reflex, pilomotor, the, 743.
Reflexes, rapid orientation in, 150.
Registration law, the unjust and burdensome, 620.
Relaxation, use of, in hypertensive states, 539.
Renal function and vascular hypertension, 663; glycosuria, 810.
Repair, economic, poise or tranquility a necessary condition of, 780.
Reprints and circulars, uniformity needed in shape and size of professional, 366.
Research, clinical, 362; clinical, an address on, 368.
Respiratory disease, acute, carriers, 453; the eye as a portal of infection in, 411; the prevention of, in infancy and early childhood, 817.
Rheumatic fever, acute, the effect of tonsillectomy on the recurrence of, 813; fever, acute, the incidence of at Bellevue Hospital, 704; nodules, the incidence and significance of the, in children, 85.
Rheumatism, chronic gonorrheal, the treatment of, by vaccines given intravenously, 412; contagion of, 492.
Rhinophyma, 247.
Rickets, 1023; the causation of, 75; the clinical rôle of the fat-soluble vitamin: its relation to, 245.

Ringworm of the nails, 770; of the scalp, 88.
Ritter, I. Sidney, and Stern, Maximilian: a new method of treating remote manifestations of gonorrheal infections, 190.
Roberts, F. A.: ureteral kinks and their significance, 437.
Robinson, Beverley; some so-called advances in the practice of medicine, 966; the inhalation treatment in pulmonary tuberculosis, 143; the treatment of influenza, 198.
Rocky Mountain spotted fever, 445.
Roentgen ray studies of bronchial function, 251; the, and tuberculosis, 1046; therapy in gynecology, 207.
Rollier's heliotherapy, see *Heliotherapy.*
Ryan, Thomas J.: in what way do focal infections cause systemic disease? 999.

S

Saccharin, 521.
Salivary ducts, calculi in, 970.
Salts, mineral, for disordered heart action, 1007.
Sarcoma of the round ligament, 652; of the stomach, with report of a case and an analysis of 86 cases operated on, 337.
Satterthwaite, Thomas E.: on some present-day cardiological topics, 305.
Scalp, ringworm of the, 88.
Scarlatinoid rashes, clinical interpretation of, 496.
Scarlet fever, quarantine and disinfection in, 34; specific nature of the hemolytic streptococci of, 927; the tonsils and, 628.
Schick reaction for the determination of susceptibility to diphtheria, 367; test, an experience with the, and toxin-antitoxin and a plea for their use in the extinction of diphtheria, 286.
Schisler, Edwin, and Meershel, H. G.: malignant endocarditis, 690.
Schlapp, Max G.: mental deficiency and criminality, 554.
Scholtz, Meses: the skin as an index to health, 824.
Sclerosis, multiple, colloidal gold test in, 149.
Scorbutus at Lille in 1917, 111; in the late war, 920.
Scurvy and beriberi, the treatment and management of disease due to deficiency of diet, 331.
Sea sickness, treatment of, 195.
Secretions, internal, disturbance of, of sex glands, 632.
Seilin, Josef: case of influenza complicated with streptococci, bronchopneumonia, endocarditis, arthritis, and empyema; with recovery, 1042.
Seminal vesicles, surgical and non-surgical treatment of the prostate and, in arthritis, 587.
Seniculture, 878.
Senile debility, treatment of, 1066.
Sepsis, epidemic, influenza or, 280; oral, see *Oral Sepsis.*
Septicemia, influenzo-pneumococcal and influenzo-streptococcal, 408.
Serological technique, 1035.
Serotherapy, antidiphtheritic, twenty-five years of, 325; of typhoid fever, 877.
Serum, antistreptococci, the use of in quinsy, 664; sickness treated with proteal, 487.
Sex glands, disturbance of internal secretion of, 632.
Shechan, Joseph Eastman: removal of a vertebra of a chicken from the esophagus, 959; ulcer of the esophagus from the standpoint of an esophagoscopist; its cause, symptomatology, diagnosis and treatment, 319.
Shell shock, scientific inquiry to be made with respect to, 1051.
Shoes, 335.
Shufeldt, R. W.: remarkable vitality in the larva of an insect (alaus oculatus), 874.
Simulators, mythomaniacal, see *Hysterical symptoms.*
Sinus, circular, the etiology and pathogenesis of rupture of the, 918.
Sinusitis, influenza and, 153.
Skin, the, as an index of health, 824.
Skull, fractures of the, civil lessons of the war for the treatment of, 1013; the surgical treatment of gummatous osteitis of the, 330.
Sleeping sickness, African, 1046; endemic, 404.
Smallpox and vaccination, history of in Venezuela, 1024.
Smoking, the barbarous custom of, 185.
Sohel, Jacob: the prevention of respiratory diseases of infancy and early childhood, 817.
Society Reports:
American Association for Thoracic Surgery, 1019, 1056; 1093.
American Laryngological, Rhinological, and Otological Society, Eastern Section, 499.

Philadelphia County Medical Society, 465, 1062.
Southern Surgical Association, 334.
Western Surgical Asseciation, 247.
Sodoku, 405.
Soldier's heart and war neuroses, a study in symptomatology, 843.
Soresi, A. L.: on the desirability of instituting a special medical board which should correspond to the Patent Office: the function of this medical board being to establish and protect the priority of ideas relating to medical subjects, 227.
Souther, Charles T.: local anesthesia in the radical cure of hernia, 274.
Spencer, Henry James, Oppenheimer, Seymour and: value of laboratory examinations in diagnosis and prognosis in otolaryngology, 7.
Spermatoceles and hydroceles containing spermatozoa, 334.
Spermatozoa, spermateceles and hydroceles containing, 334.
Spina bifida, operative technique in, 247.
Spinal cord tumors, the diagnosis of, 903.
Spirochete, new ideas on the, 295.
Spirochetosis, is influenza a, 30.
Splanchnic relaxation, treatment of by electrical currents, 828.
Spleen, hemic cysts of, 403.
Spondylitis and abdominal pain, 809.
Stammering. Underlying causes and method of correction, 914.
Stasis, chronic intestinal, in children, 157.
State Board Questions and Answers, California, 588, 671, 767; Colorado, 295, 377, 506; Nebraska, 894, 978, 1063; New York, 41; North Carolina, 124, 210.
Stein, Herbert E.: a clinical study of ectopic pregnancy; a new etiological theory, 478.
Sterility, causes of, 534; of women, endocrine treatment in the, 121; the instincts, the emotions, and the endocrines in, 383.
Stern, Maximilian, and Ritter, I. Sidney: a new method of treating remote manifestations of gonorrheal infections, 190.
Stewart, Douglas H.: dilatation and plication of the caput coli, 218.
Stimulants, cardiovascular, see *Cardiovascular.*
Stomach and duodenum, the late results of the surgical treatment of chronic ulcers of, 750; angioma of the, 220; sarcoma of, with report of a case and an analysis of 86 cases operated on, 337; surgical aspects of tuberculosis and syphilis of the, 655; syphilis of the, 79; two cases of total extirpation of the, 928.
Stone in the kidney, 336.
Stones, the results of operations for the removal of, from the ureter, 336.
Stools, a study of the, of institutional children to determine the existence of intestinal parasitic infection, 87.
Streptococci, hemolytic, in the normal throat after tonsillectomy, 367; hemolytic, specific nature of the, of scarlet fever, 927.
Stricture, hemorrhage and, of the urethra, 971; urethral, the palliative treatment of, 118.
Stump, the origin of the intrapelvic treatment of the, after supravaginal hysterectomy for fibroid tumor of the uterus, 201.
Substitute, liability for, 108.
Sumachs, poisonous, rhus poisoning, an account of, and remedies therefor, 771.
Sun treatment, the Thézac-Porsmeur method of, 663.
Sunstroke, death from, 833.
Supports, mechanical, use and abuse of, in orthopedic conditions, 926.
Surgeon-General of the Army, annual report of, 488; of the navy, annual report of, 445.
Suppurations, pulmonary, 1096.
Surgery, cerebral and spinal, anesthesia in, 231; embryology and, 338; French, 1914-1918, 159; of the head, some remarks on group study of the, 972; thoracic, importance of "vital capacity" in, 975; urological and gynecological, group study in, 974.
Sweating sickness, the symptomatology of the, 193.
Symbiotes, 447; the myth of the, 195.
Symbolism, 649.
Sympathy, human, the philosophy of, 787.
Symptoms, hysterical: modes of induction in war and peace; suggestions in normals, in confused, and in mythomaniacal simulators, 1.
Syndrome, the enterorenal, 971.
Syphilis, a comparison of two methods of administering arsenobenzol compounds in, 368; a traumatic neurosis in a case of, 288; a preliminary report on the use of a new arsenical compound in the treatment of: "men-arsone," 607; and Graves' disease, 698; and the syphilitic, some principles seldom recognized in the treatment of, 1025; and tuberculosis, 71; at a venereal clinic, 705; cerebrospinal involvement in hereditary, 81; conjugal, of the nervous system, 124; folk, in Denmark, 159; hereditary, and the new treatment, 999; in disease of the heart and circulation, 1012; malignant precocious, 698; mercuric iodide in, 770; of the kidney, 813; of the stomach, 79; primary, the Wassermann reaction in, 793; pulmonary, 766; the general prognosis of, in the light of recent progress, 290; the treatment of, by the antisyphilitic serum of Query, 927; transmission of, as an industrial disease, 839; tuberculosis and, of the stomach, surgical aspects of, 655; tuberculosis and the abortive treatment of, 706.
Syphilography in France, evolution of 29.
Syphiloma vulvæ, 165.

T

Tabes dorsalis, differential diagnosis between the pains of, and those of focal infection, 606.
Tachycardia, the meaning of, 330.
Taylor, J. Madison: poise or tranquillity a necessary condition of economic repair, 780; remedial measures conservative in most acute infectious diseases; in particular for adults and during influenza, 268; uniformity needed in shape and size of professional reprints and circulars, 366.
Teeth, the relation of, to general health, 841; the temporary: disorders due to their neglect, 854.
Test, colloidal gold, in multiple sclerosis, 149; complement fixation, for tuberculosis, 28.
Tetanus in the French army during 1918, 79; postabortive, 940.
Therapeutic hints, 88, 340, 382, 424, 550, 676, 770, 814, 1023.
Therapeutics, returning to sensible, 881.
Thézac-Porsmeur method of sun treatment, 663.
Thompson, W. Gilman: chronic aniiin poisoning, 401.
Thoracic surgery, importance of "vital capacity" in, 975; in war; lessons applicable in civil practice, 1020.
Thoracotomy from the standpoint of repair, 1022.
Thorax, report of 160 penetrating war wounds of the, 1019.
Thromboangiitis obliterans, 547; a further contribution to the etiology of, 425; the pathology of, 431; summary of the chemical blood findings in, 430.
Thrombosis, cranial, some remarks on, in children, 253.
Thymus gland, enlarged, in infancy and its treatment by radium, 77; the

treatment of malignant tumors of the, by radium, 1094.
Thyroid extract, the life-history of the first case of myxedema treated by, 64; growths, intrathoracic, diagnosis and management of, 932; operations, advantages of local anesthesia in, 932; secretion, deficient, as an etiologic factor in gastric and duodenal ulcers and in hyperacid conditions, 916; states, toxic, preliminary report on a new method for the clinical diagnosis of, 1035; surgery of the, 1053; toxic adenomata, mild types of, 633.
Thyroidectomy, technique of, 933.
Titus, Edward C.: modern treatment of obesity, 134.
Tongue, treatment of inoperable cancer of the, 158.
Tonsil and adenoid removal, an unusual case of delayed postoperative hemorrhage following, 832; chancre of, Vincent's angina simulating, 963; faucial, clinical indications for enucleation of the, 653; physiological action of extract of, 466; the, and scarlet fever, 628; the, in relation to infectious processes, 287.
Tonsillectomy, the effect of, on the recurrence of acute rheumatic fever, 813.
Toxemia, alimentary, a simple means of lessening or eliminating, 287; intestinal, in infancy: a suggested explanation, 163; its medical and surgical treatment, 398.
Transfusion, blood, a case of bacteriemia treated by, 713; in modern therapeutics, 577; in obstetrics, 265; in infants and children: the indications and dangers, 36.
Transplants, the uses of free, of the fascia lata in surgery, 331.
Treatment, expense of, before notice to employer, 20.
Treponemata, neurotropic, 1005.
Trypanosomiasis, American, in Venezuela, 498.
Trypsin intravenously, 155.
Tubal function, a method of restoring, 501.
Tubercle bacilli, dangers of infection from various common articles contaminated by, 370; on the direct cultivation of, from tissues, 412.
Tuberculosis, advanced pulmonary, the operative treatment of, 1096; and the abortive treatment of syphilis, 706; and syphilis of the stomach, surgical aspects of, 655; association, new, 240; chronic pulmonary conditions simulating advanced, 997; complement fixation test for, 28; concerning heliotherapy in, 62; differential diagnosis of, from hyperthyroidism, 670; does community responsibility end when sanatorium treatment has been given? 738; hospital, city's power to establish and receive benefactions for, 612; incidence of, in husband and wife, 969; influenza and, 250; influenza and, the relationship between, 490; latent, 317; mechanism of the compensatory factors in, 626; National Association, the antituberculosis movement in the United States prior to and since the formation of the, with brief tributes to its departed leaders, 1071; new scheme to combat, 622; of the joints, surgical experience with; Rollier's heliotherapy, 247; pulmonary, diagnostic pitfalls in, 89; pulmonary, effects of typhoid fever and typhoid vaccine on, 287; pulmonary, prognosis in, 272; pulmonary, the inhalation treatment in, 143; pulmonary, the treatment of diabetes complicated by, 811; questions, some, 283; syphilis and, 71; the roentgen ray and, 1046; what has the war taught us of? 60.
Tumors, abdominal, the diagnosis of, 138; complicating pregnancy, labor, and the puerperium, 453; complicating pregnancy, labor and the puerperium, 540; malignant, of the antrum, treatment of, 884; on the removal of large cervical, occupying the vagina, 262; of the breast, malignant and benign, 249; of the kidneys in children, observations on, 853; spinal, a clinical lecture on the surgical aspects of, 288; spinal cord, the diagnosis of, 903.
Tweddell, F.: a new remedy for influenza, 154; serum sickness treated with proteal, 487.
Twins, human, the influence of the male parent on the production of the, 549; influence of the male on the production of, 509; uniovular, 878.
Typhoid and paratyphoid incidence and deaths in the A. E. F., 462; fever, acute cholecystitis in children as a complication of, 331; fever, diagnosis of the myocarditic syndrome in, 696; fever, effects of, and typhoid vaccine on pulmonary tuberculosis, 287; fever, expert evidence as to existence of, 1002; fever, gas gangrene in, following hypodermic infusion, 339; fever in the American Army during the World War, 28; fever, serotherapy of, 877; perforation, slow evolution of, 835.
Typhus, fatal mouse, in a human subject, 570; in Poland, 277; new developments in our knowledge of, 1092.

U

Ulcer, duodenal, the symptomatology of perforated, 582; gastric and duodenal, deficient thyroid secretion as an etiologic factor in, and in hyperacid conditions, 916; gastric and duodenal, life expectancy after operations for, 109; gastric and duodenal, new views on the pathology, diagnosis and treatment of, 927; gastric and duodenal, surgical treatment of, 659; gastric, the symptoms and differential diagnosis of epigastric hernia and, 741; gastric, *x*-ray of pneumoperitoneum due to perforated, 171; of the esophagus from the standpoint of an esophagoscopist; its cause, symptomatology, diagnosis and treatment, 319; of the jejunum following gastroenterostomy, 937; peptic, the surgical treatment of, 329; simple venereal, 324.
Ulcers, chronic, of the stomach and duodenum, the late results of the surgical treatment of, 750; varicose, treatment of, 289.
Uremia, the tetanic type of, 697.
Urine, a case of suppression of, for four days, two cases of pyelitis and, 84; vitamines in the, 280.
Ureter, the results of operations for the removal of stones from the, 336.
Ureteral kinks and their significance, 437.
Uretero-ureteral anastomosis, 337.
Urethra, hemorrhage and stricture of, 971; prolapse of the, in the female, 892.
Urethral stricture, the palliative treatment of, 118.
Urological diagnosis in the practice of the general surgeon, 586.
Uterus, a new suspension operation of retroversion of, 336; bilocular, report of a case of, with carcinoma in the left horn, 604; cancer of the, radiotherapeutic and other methods of treatment of, 503; cancer of the, value of cystoscopy in, 1044; late results in the radium treatment of cancer of the, 202; some observations on subperitoneal enucleation of the: with a report of five cases, 1001; two cases of instrumental perforation of the, with rupture of the intestine, 292; *x*-ray illustrations of normal and abdominal positions of the, 294.

V

Vaccine, antigonococcic, per os, 1043; tubercle, an attenuated, 885.
Vaccinotherapy in acute staphylococcic osteomyelitis, 324.
Vaginitis, gonorrheal, in children, 1052.
Vagotonia, 238.
Vagus nerves, the integrity of the, as a factor in pneumonia, 1095.
Van Beuren, F. T., Jr.: the control of cancer. An appeal to the practitioner, 732.
Varicose veins, new method of marking the skin to show location of, at operation, 792; the post-operative complications following excision of, 1082.
Variola, progress in our knowledge of, 279.
Variolation in Spain in 1776, 149.
Veins, hepatic, the clinical diagnosis of obstruction of the, 806; varicose, new method of marking the skin to show location of, at operation, 792.
Venereal disease, early treatment of, 1010; diseases in the antenatal period, 360.
Vertigo, 625.
Vesicovaginal fistulas, the operative treatment of, 249.
Vestibular tests as an aid to the diagnosis of brain disease, with report of cases, 502.
Vincent's angina, fatal, 592; simulating chancre of the tonsil, 963; specific treatment of, 159.
Virus, filtrable, 963.
Vision, impairment of—expert examination, 192.
Visual apparatus, cosmetics of the, 928.
"Vital capacity," importance of, in thoracic surgery, 975.
Vitamine, fat-soluble, 629; fat-soluble, the clinical rôle of the, and its relation to rickets, 245; the antiscorbutic, 629; water-soluble, 630.
Vitamines, 323; in the urine, 280; internal secretions and, 741; symposium on, 629; what are? 369.
Vogel, Karl M.: Oliver Wendell Holmes and the medical student, 1067.
Vulva, carcinoma of the, no recurrence for three years, 206.

W

Walsh, William S: dreams of the feebleminded, 395.
War deaths, new totals of, 197; methods, an address on the application of, in civil practice, 330; rations and diabetes, 79; typhoid fever in the American Army during the world, 28; what has the, taught us of tuberculosis, 60; wounds of the chest, 375; wounds, see also *Wounds*.
Ward, E. H. P.: manic-depressive insanity and Raynaud's disease, 694; mortality in the animal organism. 47.
Wassermann contradictions considered from the clinical point of view, 329; reaction in primary syphilis, 793.
Water, boiling, hemangioma and lymphangioma: their response to the injection of, 935; metabolism, the evolution of recent investigations concerning, of the body in relation to the digestive secretions and the functions of the blood, 858; supply, contaminated, 1002.
Weight, child's butter fat and, 256.
Weiss, Samuel: the prophylaxis and treatment of gallstone disease, 869.
Whooping cough patients, care and treatment of, 86; see also *Pertussis*.
Wile, Ira S.: mental hygiene during childhood, 561.
Willems' method of active mobilization in surgical joints, 357.
Williams, Tom A.: encephalitis epidemica (miscalled lethargica), with special reference to diagnosis, 994; hysterical symptoms: modes of induction in war and peace; suggestion in normals, in confused, and in mythomaniacal simulators, 1.
Wine in François Rabelais' day, 233.
Women, endocrine treatment in the sterility of, 121.
Wood alcohol blindness, lumbar puncture in, 664.
Woolf, Edgar Morton: encephalitis lethargica, 494.
Workmen, the reconstruction of, after injury, 576.
Wound closure, secondary, 834.
Wounds, complications and sequelæ of war, as seen at United States Army General Hospital No. 1, 38; gunshot, of the brain with retained missiles, 334; gunshot, of the chest, the late complications of, 23; infected, observation of the Carrel-Dakin treatment of, 338; of the thorax, report of 160 penetrating war, 1019; the immediate sterilization and closure of chronic infected, 884; war, of the chest, 375, 1020.
Wright, B. L., and Kennell, L. A.: a preliminary report on the use of a new arsenical compound in the treatment of syphilis: "Mon-Arsone," 607.

X

X-ray, localization of pulmonary lobes by the, 1095; of pneumoperitoneum due to perforated gastric ulcer, 171; practice, good will of physician's, 20.

Y

Yaws, neosalvarsan (neoarsphenamine) in, 94.
Yeasts from the human colon. Protocol of laboratory studies as to pathogenicity, 693.

Z

Zuehlin, Ernest: deterioration of our cardiovascular stimulants; means of preserving and of increasing their therapeutic efficiency, 16.
Zugsmith, Edwin: some personal views of bronchial asthma, 611.
